Seeing Better but Knowing Less: Corruption-Robustness Fine-Tuning Silently Erodes Visual Abstention in Vision-Language Models

Anonymous CVPR submission

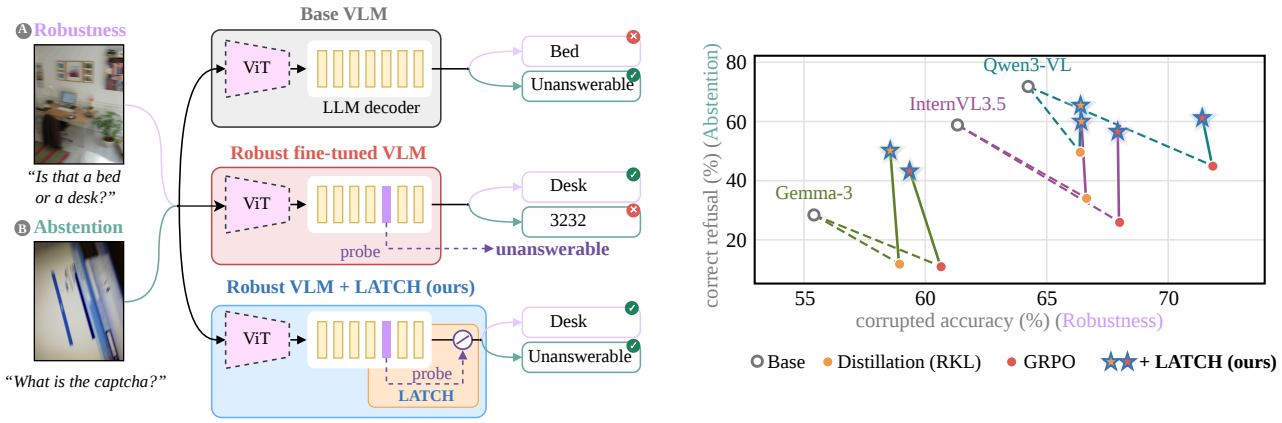

Figure 1. Corruption-robust post-training makes a VLM answer what it cannot see, although it still knows. Left: Qwen3-VL-4B on a motion-blurred GQA image (A) and an unanswerable VizWiz photo (B). Robust fine-tuning (GRPO) corrects the base model on A, but on B it answers "3232" where the base model refuses, although a linear probe on its hidden state still reads B as unanswerable. LATCH (ours) acts on this signal: it refuses on B and keeps the correct answer on A. Right: on three backbones, robust fine-tuning (RKL or GRPO) raises corrupted accuracy but lowers correct refusals on unanswerable VizWiz questions (dashed); LATCH recovers the refusals and keeps most of the accuracy gain (solid). Numbers are from Tabs. 3 and 4.

Abstract

Vision–language models (VLMs) are deployed precisely where images are hardest to read: assistive photography for blind and low-vision users, perception through rain, fog and motion blur, and low-quality clinical or scientific scans. In these settings the safe response to an uninterpretable input is not a confident guess but an admission that the image cannot support an answer. We show that the obvious way to prepare a VLM for degraded inputs—fine-tuning it for corruption robustness—silently removes this behavior. Using two standard adaptation recipes, on-policy reverse-KL distillation (RKL) and Group Relative Policy Optimization (GRPO), we find that corruption-robust training improves clean and corrupted accuracy and transfers zero-shot to corruption types never seen in training, yet drives both models to answer uninterpretable and image-free inputs far more often than the base model. The regression is invisible to accuracy: the most accurate model we train is the worst at recognizing when it cannot see. We then explain the failure. A linear probe recovers answerability from frozen hidden states at AUROC ≈ 0.93 in every model, so the ability is suppressed, not erased; and a reasoning-transplant test shows the two recipes break for opposite reasons—RKL cannot reason its way to "unanswerable," whereas GRPO reasons correctly but has learned an answer-level shortcut that commits regardless. Finally we recover abstention with LATCH (LATent CHeck), which reads this surviving signal before generation and replaces the answer by a refusal when it fires. On all six fine-tuned models, LATCH raises correct refusals on unanswerable VizWiz questions from 11–50% to 43–65% at a cost of at most 1.3 points of corrupted accuracy, outperforming both retraining with unanswerable examples and activation steering. The results argue that corruption robustness and calibrated abstention must be measured, and optimized, together.

1. Introduction

Imagine a blind person who points his phone at a medicine bottle and asks a vision–language model (VLM) [3, 12, 33, 56] how many tablets to take [4, 16]. If the photo is slightly blurred, a good model should still read the label. If the same photo is taken in a dim room with a shaking hand, and the label is unreadable, then the only safe reply is "I cannot read this; please retake the photo." Similar phenomena arises when an autonomous vehicle drives into dense fog [39, 48] or a clinical assistant reads a noisy scan [31]. A deployable trustworthy VLM therefore needs two capabilities at once. It must be robust: when corruption degrades the image but does not destroy it, the model should still answer correctly [8, 11, 19, 21, 43, 54]. And it must learn to abstain: when the corruption destroys the information, the model should say that the image cannot support an answer [7, 9, 10, 40, 57, 58].

The first capability, robustness of VLM, has been well studied through corruption-robust fine-tuning: training the model on corrupted images until it answers them correctly [18, 20, 34, 52, 59]. Mainly, two post-training frameworks dominate this field. On-policy distillation trains a student that sees the corrupted image to match a teacher that sees the clean one [1, 14, 22, 26], and reinforcement learning with verifiable rewards [15, 30], such as GRPO [36, 47], rewards answers that match the gold label. Despite raising corrupted accuracy, robust fine-tuning never accounts for the second capability, abstaining. State-of-the-art corruption-robust training framework uses label-preserving data: a corrupted image retains the label of its clean image even when the corruption has removed the information that label depends on [20, 35]. Every training example is answerable, so a refusal is never seen or rewarded, and evaluation reports accuracy alone [34, 52, 54]. This results in a silent regression (Fig. 1): on Qwen3-VL-4B, GRPO raises corrupted accuracy by 7.6 points yet lowers correct refusals on unanswerable VizWiz questions from 71.6% to 44.9%. This mirrors a known pattern, where post-training for one objective erodes a capability of base model it never touched [28, 29, 37, 42, 60]; in language models, reinforcement fine-tuning already reduces refusals on unanswerable questions [27, 50]. The obvious repair, retraining with unanswerable examples [58, 61], needs a new training run for every model and, as we show, transfers poorly from synthetic to real degradation. We therefore ask: does corruption-robust fine-tuning fully erode abstention capability of VLMs, or can it be recovered?

Our key observation is that robust fine-tuning (post-training) suppresses abstention rather than erasing it. To test whether a post-trained model still carries abstention capability, we train a simple linear classifier probe, to predict answerability from the model's internal state (layer 24 for Qwen). The probe separates answerable from unanswerable questions equally well before and after fine-tuning (AUROC ≈ 0.93, Sec. 5.4), and it correctly identifies 76–77% of the unanswerable questions that the fine-tuned models still answer. Therefore, the post-trained models still know that the image cannot support an answer, but doesn't transfer to the model's output. Our hypothesis is that either the post-trained models lack reasoning, or they reason but confidently answer wrong. Our empirical experiment (Sec. 5.5) shows that when provided with the correct reasoning for illegible images, the distilled model accurately refuses 98.4% of the time: so its failure lies in its own reasoning. For this same setting, GRPO trained model refuses only 8.2% of the time: even when the reasoning says the image is illegible, depicting learned shortcuts from sparse outcome-reward.

Our key insight is that because the answerability signal survives post-training and is available in the latent stages, we read it directly instead of retraining the model. We do this with LATCH (LATent CHeck, Fig. 2). The linear probe from our analysis, trained once per model, reads the model's internal state for the given image and question before generation begins. If it flags the question as unanswerable, the model returns a refusal; otherwise, the model answers as usual. Because LATCH reads its signal before the reasoning step, it sidesteps both failure modes above, keeping the robustness gained from post-training preserved. A single threshold on the probe's confidence sets the trade-off between correct and unnecessary refusals. We compare LATCH with activation steering, which shifts the model's internal state toward the base model during generation, and with retraining on 10% unanswerable examples, which requires a new training run for each model. Prior work either trains VLMs for robustness and reports accuracy only [18, 34, 52, 54], or measures and improves abstention on pretrained base models [38, 40, 45, 55, 62], where probes reveal unanswerability the output ignores [5, 17, 24, 41]. In contrast, we study how robust post-training changes this gap and use the latent representation retain both robustness and abstention. In summary, our contributions are:

1. We expose a silent abstention regression. On three 4B VLMs (Qwen3-VL, InternVL3.5, Gemma-3) fine-tuned with on-policy reverse-KL distillation (RKL) and GRPO, robustness improves on corrupted TextVQA, GQA and VQAv2 [13, 23, 49] and transfers to 11 unseen corruptions (Sec. 5.2), yet

correct refusals on VizWiz drop on every backbone (Sec. 5.3).
2. We show the ability is suppressed, not erased (Sec. 5.4), and that RKL loses it in its reasoning and GRPO at its answer (Sec. 5.5).
3. We restore abstention without giving up robustness. LATCH raises correct refusals on VizWiz from 11–50% to 43–65% across all six fine-tuned models, at 1.5–2.8 points of unnecessary refusals and at most 0.4 points of corrupted accuracy (1.3 on Gemma-3-4B GRPO), outperforming steering and retraining (Sec. 5.6).

2. Related Work

Visual understanding. Instruction-tuned VLMs built on strong language backbones are now the default interface for image understanding [3, 12, 56]. They are measured on VQA benchmarks targeting compositional reasoning (GQA [23]), language-prior control (VQAv2 [13]), and scene-text reading (TextVQA [49]). VizWiz [16] is unique for our purpose: its images are taken by blind users, are frequently unreadable, and a large share of its questions cannot be answered, making it the natural testbed for abstention under real-world degradation. We use these benchmarks differently from the accuracy-only protocol they are usually reported with: every accuracy number is paired with an abstention measurement, refusals on VizWiz's unanswerable questions and on copies of the other three benchmarks with the image withheld, because accuracy alone hides the regression we study.

Corruption-robust post-training. ImageNet-C [19] established common corruptions (noise, blur, weather and digital artifacts at graded severity) as the standard robustness benchmark, and Usama et al. [54] showed that VLM accuracy on TextVQA and GQA drops substantially under them. Recent work trains VLMs to close this gap [18, 34, 52], building on two post-training recipes. Distillation transfers a teacher's behavior to a student [22, 26]; for generative models, reverse-KL and on-policy variants work best [1, 14], and we combine both with a clean-image teacher and a corrupted-image student (Sec. 4.1). GRPO [47] replaces PPO's value network [46] with group-relative advantages and has become a standard recipe for fine-tuning with verifiable rewards [15, 36]. We follow the corrupted-VQA protocol of [54] but train with a different corruption engine, so 11 of the 19 evaluation corruptions are never seen in training. Neither recipe is free of side effects. Fine-tuning erodes capabilities it never targets, from safety alignment [42] to previously learned skills [28, 37, 60], and reinforcement fine-tuning reduces refusals on unanswerable questions in language models [50]. Robust post-training, however, is evaluated on accuracy alone. We show that it silently erodes visual abstention, and that GRPO does so through an always-answer shortcut that arises because its reward is defined only over answerable inputs.

Visual abstention and the representation–output gap. Knowing when not to answer is central to reliability [10, 27], and VLMs readily answer questions that the image cannot support. Several benchmarks measure this failure directly [6, 38, 40, 45, 62], and lightweight methods add abstention to a fixed model, either by estimating answer reliability [25, 51] or by attaching an unanswerability head [55]. Closest to us, two concurrent works find that VLMs know more than they say: linear probes decode answerability from hidden states even when the final answer ignores it, in physical-reasoning videos [41] and in static images [17], where Rep2Act closes the gap by fine-tuning. All of this work studies a fixed model. We show that the gap moves: corruption-robust post-training widens it, at the reasoning step for distillation and at the answer step for GRPO. Like CLIP-UP, LATCH adds a light classifier and leaves the backbone untouched, but it reads each fine-tuned model's own hidden states and, unlike Rep2Act, changes no weights.

Activation steering. Steering methods edit a model's internal activations at inference time to change its behavior [32, 53, 63]. Contrastive Activation Addition [44] adds the mean activation difference between contrasting examples during generation, and refusal in particular is often controlled by a single such direction [2]. We use contrastive steering as a baseline, with directions built from base-versus-fine-tuned responses that push the fine-tuned model back toward the base model's abstention.

3. Preliminaries and Problem Formulation

Visual question answering with abstention. Each item of a dataset $\mathcal{D}$ has an image $x \in \mathbb{R}^{H\times W\times 3}$, a question q, and a label $u \in \{0,1\}$: $u = 0$ if the image shows the answer, and $u = 1$ if it does not (it is too degraded, or withheld). An answerable item has a gold answer $a^\star$ and a set $\mathcal{A}(x,q)$ of accepted answers: the annotators' answers, or $\{a^\star\}$ on GQA. A VLM is a policy π that writes a response $y \in \mathcal{V}^T$ of T tokens, $y_t \sim \pi(\cdot \mid y_{<t}, x, q)$, ending in one <answer> block; the answer parsed from this block is $\mathrm{ans}(y)$. The refusal indicator $\mathrm{ref}(y) \in \{0,1\}$ is 1 if $\mathrm{ans}(y)$ contains a refusal phrase such as "unanswerable" (full list in Sec. 5.1).

As in selective prediction [10], we score answering and abstaining separately. With y the response from π and $\mathbb{E}_{\mathcal{D}}$ the average over a set $\mathcal{D}$ of items, the accuracy (Acc; ↑), correct-refusal rate (CR; ↑) and unnecessary-refusal rate (UR; ↓) are

$$\mathrm{Acc}(\pi;\mathcal{D}) = \mathbb{E}_{\mathcal{D}}\,\mathbb{1}[\mathrm{ans}(y) \in \mathcal{A}(x,q)]\,, \tag{1}$$

$$\mathrm{CR}(\pi;\mathcal{D}) = \mathbb{E}_{\mathcal{D}}[\mathrm{ref}(y) \mid u=1]\,, \tag{2}$$

$$\mathrm{UR}(\pi;\mathcal{D}) = \mathbb{E}_{\mathcal{D}}[\mathrm{ref}(y) \mid u=0]\,. \tag{3}$$

Corruption-robust fine-tuning. VLMs lose accuracy on degraded images [54], so a common remedy is to fine-tune them on degraded images. A corrupted image $\tilde{x}$ is x with one corruption applied, such as fog or blur. Robust fine-tuning starts from a base VLM π_0, trains on a set $\mathcal{D}_{\mathrm{train}}$ of items $(x, \tilde{x}, q, a^\star)$ to raise accuracy on $\tilde{x}$, and returns π_θ, the same model with parameters θ. This training is label-preserving: a corrupted image keeps the label of its clean image [18, 20, 35], even when strong corruption removes the information the label depends on [35]. Every training item is therefore answerable ($u = 0$), so CR never enters the training objective.

We evaluate models on two sets. The answerable set $\mathcal{D}_{\mathrm{A}}$ ($u = 0$) holds questions on clean images, on corrupted copies of them, and on real photographs that still show the answer; $\mathcal{D}_{\mathrm{A}}^{\mathrm{C}} \subset \mathcal{D}_{\mathrm{A}}$ is its corrupted part. The unanswerable set $\mathcal{D}_{\mathrm{U}}$ ($u = 1$) contains real photographs too degraded to answer and questions asked without their images (Sec. 5.1). Compared with π_0, fine-tuning raises accuracy on corrupted images, $\mathrm{Acc}(\pi_\theta;\mathcal{D}_{\mathrm{A}}^{\mathrm{C}})$, but lowers the rate of correct refusals, $\mathrm{CR}(\pi_\theta;\mathcal{D}_{\mathrm{U}})$ (Sec. 5.3).

Problem Description. Given the base model π_0, its fine-tuned version π_θ, and the evaluation sets $\mathcal{D}_{\mathrm{A}}$ and $\mathcal{D}_{\mathrm{U}}$, our goal is to recover abstention without giving up the robustness gains: find an intervention g, either retraining π_0 on modified data or an inference-time rule applied to π_θ, whose model π', evaluated on the same items, prompt and decoding as π_θ, solves

$$\begin{aligned} \max_{g}\ & \mathrm{CR}(\pi';\mathcal{D}_{\mathrm{U}}) \\ \text{s.t.}\ & \mathrm{Acc}(\pi';\mathcal{D}_{\mathrm{A}}^{\mathrm{C}}) \geq \mathrm{Acc}(\pi_\theta;\mathcal{D}_{\mathrm{A}}^{\mathrm{C}}) - \Delta_{\mathrm{acc}}, \\ & \mathrm{UR}(\pi';\mathcal{D}_{\mathrm{A}}) \leq \mathrm{UR}_{\max}, \end{aligned} \tag{4}$$

where Δ_{acc} is the tolerated loss of corrupted accuracy and $\mathrm{UR}_{\max}$ the tolerated unnecessary-refusal rate (RQ3).

Prior work either fine-tunes VLMs for corruption robustness and reports accuracy alone [18, 34, 52], or studies and adds abstention in models as released [17, 38, 40, 41, 55, 62]; to our knowledge, recovering abstention after robustness fine-tuning, without losing its gains, has not been posed (Sec. 2). The problem arises wherever a model is fine-tuned on answerable-only data ($u = 0$ throughout $\mathcal{D}_{\mathrm{train}}$) and deployed where unanswerable inputs occur, as in assistive, driving and medical imaging. It is hard for two reasons: the regression is invisible during training and on accuracy benchmarks, since CR enters neither the training objective nor Acc; and both constraints of Eq. (4) pull against the objective, because a fix that refuses more can give back corrupted accuracy or refuse answerable questions.

4. Method

Given a base VLM π_0, we make it robust to corruptions, locate what this does to its abstention, and then repair it, which solves the problem of Sec. 3, in three steps: ❶ We fine-tune π_0 on corrupted images with RKL or GRPO, which gives π_θ (Sec. 4.1). ❷ We locate where abstention is lost, which tells us what an intervention can use: a linear probe reads u from the model's hidden state (Eq. (10)), and a reasoning transplant tests whether π_θ drops the refusal in its reasoning or in its answer (Sec. 4.2). ❸ We recover abstention (Eq. (4)) with three interventions g: retraining on an unanswerable mix, LATCH, a latent check that turns the probe of step ❷ into a refusal rule, and activation steering (Sec. 4.3).

4.1. Corruption-robust fine-tuning

Both recipes train π_θ on its own sampled responses to the corrupted image $\tilde{x}$. They differ only in what scores those responses: a teacher's token distribution for RKL, a verifiable reward for GRPO.

On-policy reverse-KL distillation (RKL). Knowledge distillation trains a student to match a teacher's output distribution instead of hard labels [22]. On-policy distillation [1] lets the student sample its own responses and has the teacher score every token of them, so the student is corrected on the prefixes it reaches itself rather than on the teacher's (exposure bias). Here the student π_θ sees $\tilde{x}$, and a frozen teacher π_{teach}, a larger model of the same family, sees the clean image x. For each question we sample $N_{\mathrm{roll}} = 2$ responses $y \sim \pi_\theta(\cdot \mid \tilde{x}, q)$ and minimize the reverse KL at every position $t \in \{1, \ldots, T\}$:

$$\mathcal{L}_{\mathrm{RKL}}(\theta) = \mathbb{E}\Big[\textstyle\sum_{t=1}^{T} \mathrm{KL}\big(\pi_\theta(\cdot \mid y_{<t}, \tilde{x}, q) \,\big\|\, \pi_{\mathrm{teach}}(\cdot \mid y_{<t}, x, q)\big)\Big], \tag{5}$$

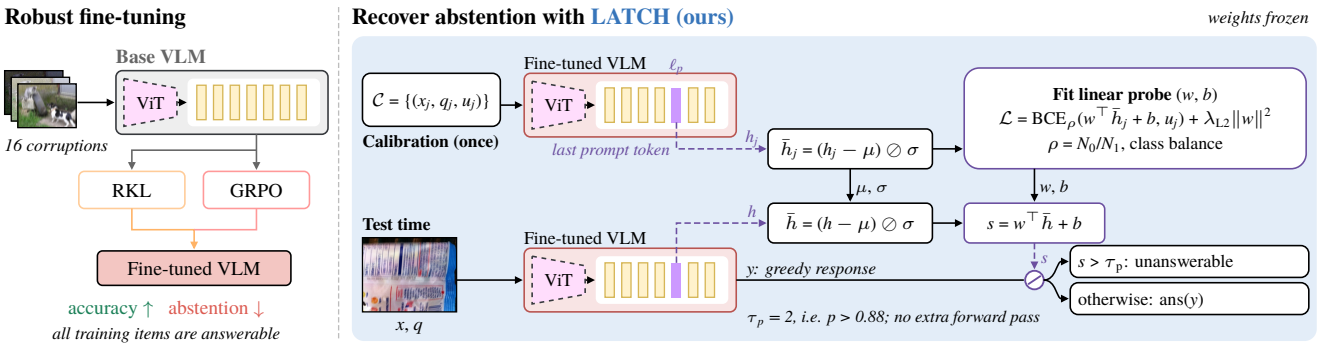

Figure 2. Overview. Robust fine-tuning (RKL or GRPO) raises accuracy but lowers abstention. LATCH restores it with frozen weights: a latent check, fitted once per model on a calibration set $\mathcal{C}$, replaces the answer by "unanswerable" when the probe logit s exceeds τ_p ($P(\text{unanswerable}) > 0.88$). (x, q): image and question; y: response; u: answerability label ($u = 1$: unanswerable); BCE_ρ: binary cross-entropy that weights the N_1 unanswerable calibration items by $\rho = N_0/N_1$, with N_0 answerable items. The two baselines are drawn in Figs. S1 and S2.

with the expectation over $(x, \tilde{x}, q) \sim \mathcal{D}_{\text{train}}$ and $y \sim \pi_\theta(\cdot \mid \tilde{x}, q)$. Each term measures how far the student's next-token distribution on $\tilde{x}$ is from the teacher's on x, after a prefix the student wrote itself. Reverse KL is mode-seeking: the student concentrates on the teacher's dominant continuations rather than covering all of them [14]. We estimate each term from the sampled token, as a policy gradient with advantage $A_t = \log \pi_{\text{teach}}(y_t \mid \cdot) - \log \pi_\theta(y_t \mid \cdot)$. RKL needs no gold answers, only teacher forward passes.

Group Relative Policy Optimization (GRPO). GRPO [47] replaces the teacher with a verifiable reward and PPO's value network with a group baseline, and it sees only $\tilde{x}$. For each question it samples $G = 8$ responses $y^{(i)} \sim \pi_{\theta_{\text{old}}}(\cdot \mid \tilde{x}, q)$, $i \in \{1, \ldots, G\}$, from the policy before the update, and scores each as

$$r_i = \mathbb{1}\Big[\mathrm{fmt}_i \wedge \mathrm{ans}(y^{(i)}) = a^\star\Big] + w_{\text{fmt}}\,\mathrm{fmt}_i, \qquad (6)$$

where $\mathrm{fmt}_i \in \{0, 1\}$ is 1 if $y^{(i)}$ has exactly one <answer> block and ends right after it, $w_{\text{fmt}} = 0.1$, and $a^\star$ is the GQA gold answer (exact match). For example, a well-formed response with the gold answer earns $r_i = 1.1$, a well-formed wrong answer 0.1, and a response cut off before its <answer> block 0. Advantages are standardized within the group,

$$\hat{A}_i = \frac{r_i - \mathrm{mean}(r)}{\mathrm{std}(r) + \epsilon_{\text{std}}}, \qquad (7)$$

and the policy maximizes the clipped surrogate with a KL anchor to the base model:

$$\mathcal{J}_{\text{GRPO}}(\theta) = \mathbb{E}\Big[\frac{1}{\sum_i |y^{(i)}|}\sum_{i,t} \min\big(\rho_{i,t}\hat{A}_i,\ \bar{\rho}_{i,t}\hat{A}_i\big) - \beta\,\mathrm{KL}(\pi_\theta \,\|\, \pi_0)\Big]. \qquad (8)$$

Here i ranges over the group and t over the tokens of $y^{(i)}$, $\rho_{i,t} = \pi_\theta(y_t^{(i)} \mid \tilde{x}, q, y_{<t}^{(i)})/\pi_{\theta_{\text{old}}}(y_t^{(i)} \mid \tilde{x}, q, y_{<t}^{(i)})$ is the ratio of the current to the sampling policy, $\bar{\rho}_{i,t} = \mathrm{clip}(\rho_{i,t}, 1 - \epsilon_{\text{clip}}, 1 + \epsilon_{\text{clip}})$, $\epsilon_{\text{clip}} = 0.2$, $\epsilon_{\text{std}} = 10^{-6}$ and $\beta = 0.04$; the token mean is taken over all groups of an optimizer step. Because every training item has $u = 0$, a well-formed refusal scores like any wrong answer ($r_i = 0.1$), and its advantage is negative whenever another response in its group is correct: no term of Eqs. (6) and (8) ever rewards abstaining.

4.2. Locating the loss

We next ask where the refusal is lost: in the representation of answerability, in the reasoning, or in the answer.

Answerability probe. For a model π and decoder layer $\ell \in \{1, \ldots, L\}$, one prefill gives the residual-stream state $h_\pi^{(\ell)}(x, q) \in \mathbb{R}^d$ at the last prompt token, the position just before the response begins. We standardize each of its d features, $\bar{h} = (h_\pi^{(\ell)}(x, q) - \mu) \oslash \sigma$ with $\oslash$ element-wise division, by the mean μ and standard deviation σ over a labeled calibration set $\mathcal{C} = \{(x_j, q_j, u_j)\}_{j=1}^{N_c}$, so that one L2 strength penalizes all features on the same scale. We then fit a class-balanced, L2-regularized logistic regression

$$p_\ell(u = 1 \mid x, q) = \mathrm{sigmoid}\big(w^\top \bar{h} + b\big), \qquad (9)$$

one per model and layer, on that model's own states; class balancing offsets the unequal class sizes of $\mathcal{C}$. The AUROC of the logit $w^\top \bar{h} + b$ on held-out items, $\mathrm{AUROC}_\ell(\pi) \in [0, 1]$, measures how well layer ℓ of π encodes u; the same probe fitted on shuffled labels gives its chance floor. We say the probe flags an input when

the logit exceeds 0. Because the probe reads the state from which the response starts, it tests whether

$$\begin{aligned} &\mathrm{AUROC}_\ell(\pi_\theta) \approx \mathrm{AUROC}_\ell(\pi_0) \\ &\text{while}\ \ \mathrm{CR}(\pi_\theta; \mathcal{D}_\mathrm{U}) < \mathrm{CR}(\pi_0; \mathcal{D}_\mathrm{U}), \end{aligned} \tag{10}$$

i.e. whether π_θ still encodes that the input is unanswerable when it begins to answer. If so, the failure is behavioral rather than representational (RQ1), and an intervention can use the signal that survives.

Reasoning transplant. A refusal can be lost in the reasoning, which never concludes that the image is insufficient, or in the answer, which ignores reasoning that does. For example, on a blurry VizWiz photo of jellybeans the RKL response lists flavors it cannot see, a reasoning-side failure, while on Fig. 1B the GRPO response states that the text "cannot be deciphered with certainty" and still gives ans(y) = "3232", an answer-side failure. To separate the two at scale, we take the unanswerable items that π_θ answered and π_0 refused, prefill π_θ with (x, q) followed by π_0's response up to and including <answer>, and record whether π_θ's answer is a refusal. If π_θ now refuses, its answer step follows a "can't-tell" chain, so its failure is that its own reasoning never produces one; if it still answers, its answer step overrides the reasoning. Further details on this is given in Sec. 5.5

4.3. Recovering abstention

We finally ask how to bring the refusal back without giving up the gains of step ❶. Each remedy is an intervention g in Eq. (4): the first changes the training data, and the other two keep θ fixed and act at inference. On the captcha question of Fig. 1B, the mix makes a refusal the trained target for images corrupted past recognition, LATCH replaces "3232" by a refusal when the probe flags (x, q), and steering moves the hidden states of π_θ toward those of π_0 while it writes.

Unanswerable mix. The first remedy asks whether abstention was lost simply because the training signal never contained it. We retrain π_0 from scratch with the same recipe and budget on a mix in which 10% of the questions are unanswerable: GQA images corrupted far past recognition, with $a^\star$ = "unanswerable" (Destroyed-GQA, Sec. 5.1; see Fig. S1). Abstaining is then imitated (RKL, whose teacher sees the same destroyed image) or rewarded (GRPO, where a well-formed refusal on these items now earns $r_i = 1.1$ in Eq. (6)).

Algorithm 1 LATCH: one linear read of the prompt replaces an answer by a refusal. Lines 1–3 run once per model; lines 4–8 add no forward pass.

Require: model π, layer ℓ_p, calibration set $\mathcal{C} = \{(x_j, q_j, u_j)\}$, L2 strength λ_{L2}, cutoff τ_p

1: $h_j \leftarrow h_\pi^{(\ell_\mathrm{p})}(x_j, q_j)$ for every j ▷ prefill only
2: $\mu, \sigma \leftarrow$ mean and std. of $\{h_j\}$; $\bar{h}_j \leftarrow (h_j - \mu) \oslash \sigma$
3: $(w, b) \leftarrow$ fit Eq. (9) to $\{(\bar{h}_j, u_j)\}$, class-balanced, L2 strength λ_{L2}
4: On a test input (x, q): prefill and read $\bar{h} \leftarrow (h_\pi^{(\ell_\mathrm{p})}(x, q) - \mu) \oslash \sigma$
5: $y \leftarrow$ greedy response of $\pi(\cdot \mid x, q)$ ▷ reuses the prefill
6: if $w^\top \bar{h} + b > \tau_\mathrm{p}$ then
7: return "unanswerable"
8: return ans(y)

Algorithm 2 Contrastive activation steering pushes the fine-tuned model back toward the base model's refusal. Shown for the image-contrast vector; the no-image vector changes lines 1–3 (see text). The weights are never modified.

Require: base π_0, fine-tuned π_θ, pool $\mathcal{P}$ of unanswerable VizWiz-train items, layer ℓ_s, scale α, gate threshold τ_H ($\tau_\mathrm{H} < 0$: always on)

1: $\mathcal{S} \leftarrow \{(x, q) \in \mathcal{P} : \mathrm{ref}(y_0) = 1,\ \mathrm{ref}(y_\theta) = 0\}$, with y_0, y_θ the greedy responses of π_0, π_θ
2: For each $(x, q) \in \mathcal{S}$, run (x, q, y_θ) through both models; collect $h_{0,t}^{(\ell_\mathrm{s})} - h_{\theta,t}^{(\ell_\mathrm{s})}$ at every response position t
3: $v \leftarrow$ mean of the collected differences, $v \in \mathbb{R}^d$
4: On a test input, generate from π_θ; at each decoding step t:
5: if $\tau_\mathrm{H} < 0$ or $H_{t-1} > \tau_\mathrm{H}$ then
6: $h_{\theta,t}^{(\ell_\mathrm{s})} \leftarrow h_{\theta,t}^{(\ell_\mathrm{s})} + \alpha v$

LATCH (LATent CHeck). The probe of Sec. 4.2 still reads u after fine-tuning (Sec. 5.4), so the second remedy acts on it directly (Fig. 2 and Alg. 1). Lines 1–3 fit that probe at a single layer ℓ_p, once per model and on that model's own states. Lines 4–5 run the model unchanged and reuse its prefill for the probe. Lines 6–7 replace the answer by a refusal when the probe logit exceeds τ_p; line 8 otherwise returns the model's own answer. Thus LATCH changes ans(y) only on inputs it flags, so the robustness gained on answerable inputs is kept wherever it does not fire, and τ_p sets the trade-off between CR and UR in Eq. (4).

Activation steering. The third remedy also uses the intact representation, but changes the hidden states instead of reading them (Alg. 2 and Fig. S2). We write $h^{(\ell)}_{0,t}$ and $h^{(\ell)}_{\theta,t}$ for the layer-ℓ states of π_0 and π_θ at response position t. Line 1 keeps exactly the calibration questions on which fine-tuning broke abstention, so that the vector captures what fine-tuning changed rather than refusal in general. Line 2 feeds the same text (image, question and π_θ's own response) through both models, so that the difference reflects the two models rather than two inputs. Line 3 averages over every response position of every selected question. Thus $v \in \mathbb{R}^d$ points from the fine-tuned model's over-confident state toward the base model's "this image does not support an answer" state. The no-image vector targets a missing image instead: it pairs questions asked without their image on which π_0 refuses and π_θ answers, runs the question followed by the base refusal and the question followed by the fine-tuned answer through π_θ, and averages the difference of the response-averaged states. Lines 4–6 add αv to the residual stream at layer ℓ_s on generated tokens only, upstream of the layers where answerability is most decodable, so that the push lands before the tokens that commit to an answer. The optional gate (line 5) steers only after uncertain steps, where the entropy $H_{t-1} = -\sum_{z\in\mathcal{V}} p_{t-1}(z) \log p_{t-1}(z)$ of the previous next-token distribution of π_θ exceeds τ_H; it uses step $t-1$ because the distribution at step t depends on the push itself. We gate RKL, whose failure lies in its reasoning (Sec. 5.5), so that the push corrects confused steps and leaves fluent ones alone; GRPO's failure is a uniform answer-level shortcut, so its push is always on. All calibration data come from training splits with no evaluation overlap.

5. Experiments

5.1. Experimental setup

Metrics. We report the three quantities of Sec. 3, all in %. A response is a refusal, $\mathrm{ref}(y) = 1$, if $\mathrm{ans}(y)$ contains "unanswerable", "cannot", "unable", "not possible", "impossible", "no image", "not visible", "not provided" or "not determin". Accuracy (Eq. (1)) is measured on clean and on corrupted images: training uses corrupted images, so clean accuracy checks that the model has not lost what it could already do. A prediction is correct if $\mathrm{ans}(y)$ matches the answer (GQA) or any of the ten annotator answers (TextVQA, VQAv2, VizWiz), and is not a refusal. The second condition matters because some annotators answer "unanswerable" even on questions labeled answerable (46% of answerable VizWiz questions, 10% of TextVQA questions); without it, a remedy that refuses more would also appear to answer better. Correct refusals (CR, Eq. (2); higher is better) are measured on unanswerable VizWiz questions, and no-image refusals are the same rate on TextVQA, GQA and VQAv2 questions asked with the image withheld (mean of the three), where any answer is a guess from language priors. Unnecessary refusals (UR, Eq. (3); lower is better) are measured on answerable VizWiz questions. We also report answerable and unanswerable accuracy on VizWiz; because VizWiz has ten annotator answers per question, unanswerable accuracy also credits non-refusal answers that some annotators gave.

Benchmarks. We use one short name per evaluation set (Tab. 1). TextVQA-C, GQA-C and VQAv2-C are TextVQA, GQA and VQAv2 corrupted with the standard ImageNet-C engine [19]: 19 types in 4 groups (noise, blur, weather, digital) at severities 1–5; TextVQA, GQA and VQAv2 denote the same questions on clean images. VizWiz [16] is not corrupted synthetically: its 4,319 validation photographs (2,934 answerable, 1,385 unanswerable) are blurry, badly framed or dark from how blind users captured them, and it is our only source of real degradation and real unanswerable questions. No-image is TextVQA, GQA and VQAv2 with the image withheld. The comparison is fair in three ways. Every model is evaluated on the same rendered images, because each corruption is seeded per question. Training and evaluation use different corruption engines by design: only 8 of the 19 evaluation types have a training counterpart, so the other 11 (∼58% of corrupted questions) are unseen by every model. All models are decoded greedily with the same 768-token limit, and the retrained models use the same number of optimization steps as the runs they are compared with. All the models and their retrained versions were evaluated using the same prompt. We only add a single line to the prompt, "If the image does not contain enough information to answer, the answer is unanswerable.", when we are evaluating on the VizWiz dataset or on the dataset without any image.

Models and training. We study three 4B-parameter instruction-tuned VLMs: Qwen3-VL-4B-Instruct [3], InternVL3.5-4B [56] and Gemma-3-4B-it [12], written Qwen3-VL-4B, InternVL3.5-4B and Gemma-3-4B below. For RKL, each student is paired with a larger frozen teacher from its own family, which shares its tokenizer and chat template: Qwen3-VL-8B-Instruct, InternVL3.5-14B and Gemma-3-12B-it, respectively. All models are trained on 30,000 questions drawn uniformly at random from GQA train_balanced [23]

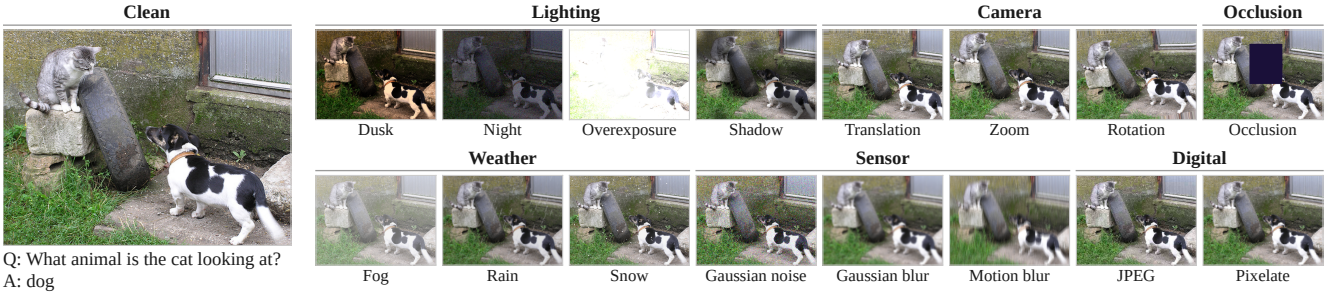

Figure 3. Training data: one GQA question under all 16 corruptions. A real question from our GQA training set, shown clean and under every corruption style at severity 4, the severity used for training, grouped into six families (lighting, camera, occlusion, weather, sensor, digital). Each training question receives one style, assigned uniformly (1,875 of the 30,000 questions per style); the question and answer are unchanged.

Table 1. Training and evaluation deliberately use different corruption engines. #Q: number of questions.

Set	Source	#Q	Role / corruption
GQA train	GQA tr. bal.	30,000	train; 16 types
Destroyed-GQA	GQA tr. bal.	3,334	10% mix; 7 types
TextVQA-C	TextVQA val	5,000	eval; ImageNet-C
GQA-C	GQA testdev	12,578	eval; ImageNet-C
VQAv2-C	VQAv2 val	5,000	eval; ImageNet-C
VizWiz	VizWiz val	4,319	eval; real (2934/1385)
Probe calib.	VizWiz train	1,901	probe; 1101 unans./800 ans.
Steering calib.	train splits	—	vectors; all 4 eval sources

(22,607 distinct images), each paired with its clean image x and one corrupted copy $\tilde{x}$. Corruptions come from our own engine of 16 types: lighting (dusk, night, overexposure, shadow), camera (translation, zoom, rotation), occlusion, weather (fog, rain, snow), sensor (Gaussian noise, Gaussian and motion blur), and digital (JPEG, pixelation). The lighting, camera, occlusion and weather types follow ROVA [18]; the sensor and digital types follow ImageNet-C [19]. All are applied at severity 4 of 5, balanced (1,875 questions per type) and seeded per question, so all models see identical images. Corruptions preserve image size, so both views yield the same number of visual tokens. Every run fine-tunes all weights for one epoch (3,750 steps of 8 questions) with the same settings on every backbone (Tab. S2). All experiments run on NVIDIA GH200 Grace Hopper superchips, each pairing a 144 GB HBM3e Hopper GPU with a 72-core Arm Neoverse-V2 Grace CPU. Each training run uses one node with two superchips: one GPU hosts the vLLM rollout server (and, for RKL, the frozen teacher), and the other runs the trainer. Evaluation, steering and probing jobs use a single GPU each.

Paired evidence-removal test. To test whether a model abstains because the evidence is missing, we build TextVQA-Paired, which asks the same question about three versions of one image: the original; a removed version in which every occurrence of the answer text is erased, so the correct response is to abstain; and a control version in which a region of identical shape and size is erased elsewhere in the image, in a place with no text, so the answer stays visible. The control receives exactly the same kind of edit as the removed image, so abstaining on the removed image while answering the control shows a response to missing evidence rather than to the edit itself. We start from TextVQA val questions whose answer is given by at least 6 of 10 annotators, is not yes/no, does not appear in the question, and matches exactly one OCR token. The removal mask is the union of that token's OCR box and every occurrence of the answer grounded by Qwen3-VL-8B-Instruct, each box padded by $\max(3\,\text{px}, 0.15h)$. The control mask is the same set of rectangles rigidly shifted by at least 20% of the image diagonal onto a text-free region with the closest pixel standard deviation. Both regions are filled with the same inpainting, and all other pixels are unchanged; the median mask covers 0.95% of the image. We keep an item only if Qwen3-VL-8B-Instruct answers the original and the control correctly and fails on the removed image, and sample 500 items. After excluding 3 items whose answer is still visible elsewhere and 29 that can be guessed from the question alone, 468 remain. All three images use the VizWiz prompt (which allows unanswerable) and the strict rule. We report original and control accuracy, evidence-removed accuracy (the abstention rate on the removed image), and paired consistency (correct on the original and the control and abstaining on the removed image).

Figure 4. Destroyed-GQA. One real item per destroyed style: the original GQA image (top) and the training input (bottom), corrupted far beyond the 1–5 severity scale (severity 100; 50 for snow). The answer is replaced by "unanswerable"; the 3,334 items make up 10% of the unanswerable mix.

Table 2. Both base models refuse almost every Destroyed-GQA image, which makes these images reliable "unanswerable" supervision. Refusal rates of the 4B base model and its 8B teacher at destruction strength.

Type	Severity	#Q	4B refuses	8B refuses
Gaussian noise	100	477	100%	100%
Gaussian blur	100	477	96%	100%
motion blur	100	476	92%	100%
rain	100	476	96%	100%
overexposure	100	476	88%	100%
night	100	476	92%	92%
snow	50	476	92%	92%

Unanswerable mix. We add 3,334 unanswerable questions to the 30,000 above, so that 10% of the 33,334-question mix is unanswerable. They come from GQA train_balanced images that are used neither in training nor for steering, one question per image. Each image is destroyed by pushing one of our corruptions far beyond the 1–5 scale: severity 100 (20× severity 5) for Gaussian noise, Gaussian blur, motion blur, overexposure, night and rain, and severity 50 for snow (Tab. 2). The question keeps its wording, its target answer becomes "unanswerable", and for these items the teacher also receives the destroyed image, so it has no access to the answer either. Every question in the mix, answerable or not, has the VizWiz instruction appended: "If the image does not contain enough information to answer, the answer is unanswerable." The mix is shuffled once (seed 1). The retrained models use the same number of optimization steps as the original runs, so compute is matched, and each sees about 90% of the mix, including roughly 3,000 unanswerable questions in expectation.

Remedy settings. LATCH (Alg. 1): ℓ_p is decoder layer 24 of 36 in Qwen3-VL-4B, Gemma-3-4B and InternVL3.5-4B, $\lambda_{L2} = 0.1$, and the cutoff probability is $p_c = 0.88$ ($\tau_p = 2$ on the logit). The calibration pool $\mathcal{C}$ is drawn from the VizWiz train split (1,101 unanswerable and 800 answerable questions, labeled by VizWiz's answer type), sharing no question or image with any evaluation set. LATCH is applied to every item of every benchmark, and an answer it replaces is scored like any other, so a false refusal on an answerable question counts as an error. Activation steering (Alg. 2): $\ell_s = 18$ of 36 layers, upstream of the best probe layers (23–24, Sec. 5.4); $\alpha = 8$ for the image-contrast vector and $\alpha = 1$ for the no-image vector. The no-image vector uses 150 pairs per dataset; only 184 VizWiz-train pairs qualify for GRPO, against 1,365 for RKL, because GRPO already refuses most no-image VizWiz questions. RKL is steered with the entropy gate at $\tau_H = 0.5$ nats, GRPO always on.

5.2. Robustness and its zero-shot transfer

Table 3 reports clean and corrupted accuracy. GRPO is strongest on every backbone, raising corrupted accuracy over the base model by 7.6 (Qwen3-VL-4B), 6.6 (InternVL3.5-4B) and 5.2 points (Gemma-3-4B), and also raising clean accuracy; on Qwen3-VL-4B its largest gains are on GQA-C (+10.2) and VQAv2-C (+9.5, per-benchmark numbers in Tab. S4). RKL improves corrupted accuracy by 2.1–5.3 points and holds clean accuracy flat on Qwen3-VL-4B. The gains transfer to corruption types never seen in training (Fig. 5): on the 11 unseen types GRPO gains 8.7 points on average, against 8.2 on the 8 seen types, and RKL gains 1.9 against 2.2. The only negative point estimate, RKL on speckle noise (-1.7 ± 2.1), is within noise. Robust

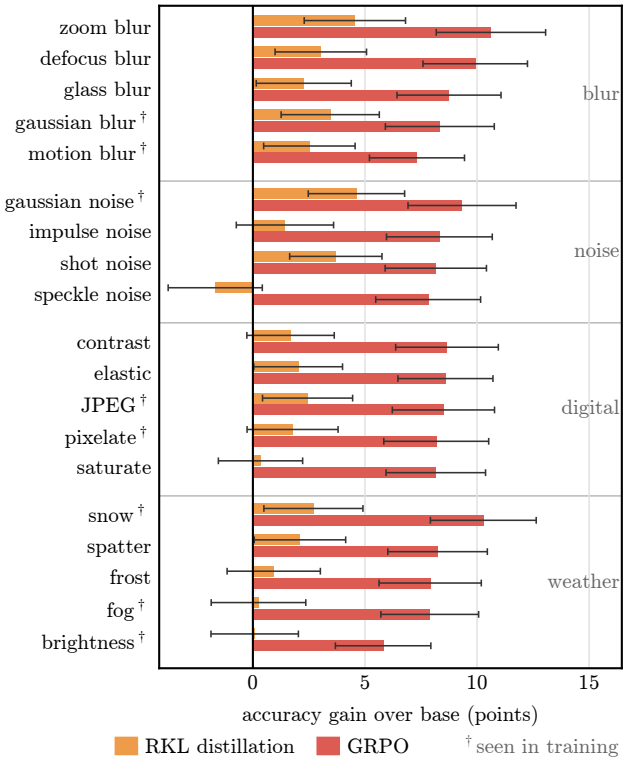

Figure 5. Both recipes' gains transfer to corruption types never seen in training. Accuracy gain of Qwen3-VL-4B over its base model per corruption type, pooled over the TextVQA-C, GQA-C and VQAv2-C questions of each type (all five severities, ∼1,190 questions per type). Error bars: 95% CI of the paired difference. †: type seen in training.

fine-tuning therefore does what it is meant to do, and it generalizes.

5.3. The silent abstention regression

The same training degrades abstention, first on real degradation and then, more sharply, on missing images. VizWiz unanswerable accuracy (Tab. 4) falls from 76.0 (base) to 60.3 (GRPO) and 56.5 (RKL) for the Qwen backbone. With the image withheld, base accuracy sits near the floor (1.9–14.5), but the fine-tuned models answer anyway, GRPO reaching 46.0 on VQAv2 and 36.3 on GQA. We see a similar kind of pattern for the other backbones as well where the fine tuned model regressed when it comes to answering questions when the answer is not there. All this scores are address in Tab. 4

5.4. RQ1: Is answerability erased, or only suppressed?

The probe of Eq. (9), fitted at every layer on the VizWiz-train pool $\mathcal{C}$ (Sec. 5.1), separates answerable from unanswerable VizWiz-val questions at AUROC ≈ 0.93 in the base, RKL and GRPO models of Qwen3-VL-4B, far above the shuffled-label control (Tab. 5): fine-tuning does not erase the representation of answerability. Among the unanswerable questions the fine-tuned models wrongly answered, the probe still flags 76–77% as unanswerable (711 items for RKL, 765 for GRPO). The models internally "know" these inputs are unanswerable, yet answer them. The lone exception is

Table 3. Robust fine-tuning raises clean and corrupted accuracy on every backbone, and GRPO gains most.

image-missingness: with the image withheld (Tab. 6) the flag rate collapses for RKL (GQA 68% → 31%), so RKL has partly lost its sense that the image is gone, while GRPO keeps it. The failure is thus one of behavior, not knowledge.

5.5. RQ2: Do the two recipes fail the same way?

They fail oppositely (Tab. 7). Handed the base model's "can't-tell" chain by the reasoning transplant (Sec. 4.2), RKL refuses 98.4% of the time, so its failure is that its own reasoning never reaches that chain. In this case, we look only at the first word π_θ would write after <answer> and if its most likely word is a refusal (e.g., "unanswerable" or "cannot"), we count it

Table 5. Answerability stays linearly decodable after fine-tuning (Qwen3-VL-4B, VizWiz val). Shuffled: AUROC of the same probe trained on shuffled labels. The best layer is chosen by VizWiz-val AUROC, i.e. on the evaluation split.

Model	Best layer	Probe AUROC	Shuffled
Base	23	0.931	0.48
RKL	24	0.927	0.52
GRPO	23	0.930	0.50

Table 6. RKL loses much of its sense that the image is missing. Share (%) of questions asked without their image that the probe flags as unanswerable (Qwen3-VL-4B).

Model	GQA	VQAv2	TextVQA	VizWiz
Base	68	75	98	100
RKL	31	38	94	99
GRPO	56	64	98	100

Table 7. RKL fails on the reasoning side, GRPO on the answer side. Reasoning transplant (Sec. 4.2, Qwen3-VL-4B): share of items the fine-tuned model refuses when given the base model's "can't-tell" chain.

Model	Items	Refuses w/ "can't-tell" chain
RKL	308	98.4%
GRPO	389	8.2%

as a refusal. Consistently, RKL's responses on these items are far longer than the base model's or GRPO's: on the unanswerable set its median response is 98 tokens against 71 (base) and 77 (GRPO), and on the subset where it runs long the gap widens to 341.5 tokens against ∼109 for both others on the same questions —the signature of an unsure, high-entropy chain that talks itself into an answer, often running to the 768-token limit. GRPO, given the identical chain, still answers 91.8% of the time: its reasoning is sound, but it has learned an answer-level shortcut, committing to a definitive answer no matter what the chain concludes, because the exact-match reward always paid off for answering. In short, RKL cannot reason its way to unanswerability; GRPO reasons there but will not act on it.

5.6. RQ3: Recovering abstention without losing the gains

On every fine-tuned model, LATCH restores abstention best. It refuses when the probe's predicted probability that a question is unanswerable exceeds a cutoff p_c; Tabs. 3 and 4 use $p_c = 0.88$. At this cutoff it raises correct refusals on VizWiz from 11–50% to 43–65% (16–38 points) while adding only 1.5–2.8 points of unnecessary refusals, and it costs at most 0.4 points of corrupted accuracy (1.3 on Gemma-3-4B GRPO) and at most 1.4 points of answerable accuracy. The unanswerable mix and steering approach or exceed its correct refusals only on Qwen3-VL-4B and InternVL3.5-4B RKL, and only at 13–18% unnecessary refusals. LATCH is also the only inference-time remedy that consistently flags a missing image (4–93% of no-image questions, against at most 3.4% for steering). Lowering the cutoff trades accuracy for recall: $p_c = 0.73$ reaches 62–77% correct refusals at 8–14% unnecessary refusals, and $p_c = 0.5$ reaches 81–88% at 17–23%, at a cost of 0.9–8.9 corrupted points.

The reason is that robust fine-tuning suppresses abstention in the model's output but leaves answerability linearly decodable from its residual stream. LATCH reads this signal once, before generation, and leaves the answer untouched when it does not fire, so the robustness gained on answerable inputs is preserved, and a single threshold sets the trade-off ($\tau_p = 0$ is the cutoff $p_c = 0.5$ above).

Steering reads the same representation but acts through one fixed direction added during decoding, so triggering refusals and preserving answers conflict. On Qwen3-VL-4B RKL, always-on no-image steering reaches 88.6% correct refusals but refuses 45.4% of answerable questions and loses 8.9 points of accuracy. Steering is also fragile across models: the best direction differs between models, and on Gemma-3-4B no configuration raises correct refusals by more than 7 points, whereas LATCH, unchanged, lifts them from 11–12% to 43–50%.

Retraining helps without test-time machinery, but it needs a full training run and recovers less, because its unanswerable examples are GQA questions on destroyed images, while real VizWiz questions are unanswerable for subtler reasons (blur, framing, an object out of view). It also barely teaches refusal on a missing image (0.8–2.2%, except 31% for Qwen3-VL-4B GRPO). RKL absorbs the mix better than GRPO: the student is pulled toward a teacher that refuses readily on destroyed images (RKL gains 13–29 points), whereas GRPO sees the label only through a sparse exact-match reward (InternVL3.5-4B GRPO gains 5 points).

Overall, abstention remains recoverable after robust fine-tuning, and the cheapest remedy works best: one logistic regression on 1,901 calibration questions, with no retraining and no change to decoding.

Table 8. TextVQA-Paired (n=468, strict scoring). Orig./Ctrl.: accuracy on the original and control images. Rem.: evidence-removed accuracy (abstention rate when the answer is erased). Cons.: correct on original and control and abstaining on the removed image. -10%: trained with 10% destroyed images labeled unanswerable. †No-image steering (λ=1, layer 18) and LATCH (τ=2), fixed from the VizWiz experiments; HuggingFace decoding, whose unsteered baseline is within 1.1 points of the row above. ‡Gemma: exact full-vocabulary RKL.

5.7. Paired evidence-removal test

Table 8 reproduces the VizWiz trade-off under a controlled edit. The edit itself is harmless: original and control accuracy agree within 3 points for every model, and unsteered models refuse at most 3.6% of controls. Fine-tuning roughly halves evidence-removed accuracy on all backbones (GRPO: Qwen 50.6 → 24.8, InternVL 35.7 → 15.4, Gemma 16.0 → 9.4) while original accuracy rises or stays flat, so models guess rather than abstain when the evidence is gone. The cause is the objective, not the corrupted data: RKL retains more abstention than GRPO on every backbone (41.7, 28.0, 12.2), and GRPO trained on clean images abstains even less (17.9). Adding 10% unanswerable images restores RKL to roughly base-model abstention (45.7, 36.1, 16.5) but lowers it further for GRPO (22.2, 6.6, 4.7). Both fixes transfer: LATCH adds 4–13 points at ≤ 0.7 points of original accuracy, and separates removed from control images as well as from originals (AUROC within 0.3), so it detects missing evidence rather than the edit; no-image steering returns Qwen GRPO to base-model abstention (49.6) at negligible cost, and gives the largest gains on RKL (73.1 Qwen, 54.1 InternVL) at a cost of 5–11 accuracy points. Neither fix helps much on Gemma, whose base model abstains on only 16% of removed images.

5.8. Is corrupted training data the cause?

GRPO is trained on corrupted images, so the abstention loss could come from the corruptions themselves (e.g., the model learning to answer through heavy noise) rather than from the objective. To separate the two, we retrain Qwen3-VL-4B with GRPO under the identical recipe and change only the training images: the same 30k GQA questions, in the same order and with the same seed, are paired with their original clean images instead of the severity-4 corruptions. All other settings are unchanged (3,750 steps, batch 8, 8 rollouts per question, learning rate 10^{-6} with cosine decay, strict exact-match reward plus 0.1 format reward, KL penalty β=0.04 to the frozen base model). Table 9 shows two results. First, the corruptions are not needed for robustness: the clean-image model never sees a corrupted image, yet matches the corrupted-image model on corrupted accuracy (71.7 vs. 71.8) and has the same clean-to-corrupted gap (7.4 vs. 7.2, base 7.8). The robustness gain is therefore a general accuracy gain that carries over to corrupted inputs. Second, the corruptions do not cause the abstention loss: clean-image GRPO abstains even less than corrupted-image GRPO on every measure, namely CR (27.9 vs. 44.9), refusal

	Accuracy			VizWiz				Abstention	
Model	Corr.↑	Clean↑	Gap↓	Ans.↑	UR↓	CR↑	Unans.↑	No-img↑	Rem.↑
Base	64.3	72.1	7.8	40.6	12.8	71.6	76.0	98.3	50.6
GRPO, corrupted images	71.8	79.0	7.2	60.9	3.2	44.9	60.3	87.1	24.8
GRPO, clean images	71.7	79.1	7.4	62.8	1.1	27.9	48.2	72.4	17.9
GRPO, clean images, intermediate checkpoints									
step 1250	71.2	78.6	7.4	64.5	1.1	25.5	45.1	51.4	14.3
step 2500	71.6	78.9	7.2	63.4	1.5	30.3	49.4	72.0	20.7

Table 9. Clean- vs. corrupted-image GRPO (Qwen3-VL-4B, identical recipe, strict scoring). Corr./Clean: mean accuracy over TextVQA-C, GQA-C and VQAv2-C; Gap = Clean − Corr. VizWiz: accuracy on answerable (Ans.) and unanswerable (Unans.) questions, unwarranted refusal on answerable (UR) and correct refusal on unanswerable (CR) questions. No-img: refusal rate on VizWiz questions with the image withheld. Rem.: evidence-removed accuracy on TextVQA-Paired (Sec. 5.7).

without an image (72.4 vs. 87.1) and evidence-removed accuracy (17.9 vs. 24.8). It answers more answerable VizWiz questions (62.8 vs. 60.9) and almost never refuses them (UR 1.1). Every intermediate clean-image checkpoint also abstains less than the final corrupted-image model, so the result does not depend on where training is stopped. The abstention loss is thus driven by the answer-focused GRPO objective; if anything, training on corrupted images, where some evidence is genuinely unreadable, partly preserves the model's willingness to abstain.

5.9. Qualitative example

Figure 1 shows the aggregate behavior on two Qwen3-VL-4B items. On the GQA question under severity-5 motion blur (A), the base model answers "bed"; GRPO recognizes the office workstation and gives the gold answer "desk"; and LATCH keeps that answer, because the probe logit (-5.93) is below τ_{p}. On the unanswerable VizWiz question (B), the base model writes that the image is "too blurry and distorted to read any text" and answers "unanswerable". The GRPO model writes that the text "cannot be deciphered with certainty" and then answers "3232", the answer-side shortcut of Sec. 5.5: its reasoning reaches the right conclusion and its answer ignores it. The probe logit on this item (3.915) exceeds τ_{p}, so LATCH replaces the answer by a refusal. The RKL failure is of the other kind: on a blurry VizWiz photo of jellybeans, it describes the flavors as "clearly visible" and answers "Cherry, Lime, Orange, Strawberry", matching the reasoning-side failure of Sec. 5.5.

6. Discussion and Conclusion

A common way of training VLMs for corruption robustness quietly makes them worse at admitting when they cannot see; standard accuracy benchmarks miss the regression; and it is recoverable. The failure is behavioral, not representational (RQ1): answerability stays linearly decodable after fine-tuning. The two dominant recipes fail for opposite reasons (RQ2): RKL on the reasoning side, GRPO on the answer side via a reward-induced shortcut. And because the knowledge survives, it can be put back to work (RQ3): LATCH reads it before generation and restores correct refusals on every fine-tuned model, at a cost of at most 1.3 points of corrupted accuracy, while the corruption gains still transfer zero-shot.

That fine-tuning for one capability silently erodes another, in a direction invisible to the metric being optimized, echoes what is seen when fine-tuning erodes safety alignment [42], and is a pattern we expect to recur wherever a training signal is defined only over answerable inputs. The practical message is simple but consequential: wherever a confident wrong answer is dangerous, corruption robustness and calibrated abstention must be measured, and optimized, together.

Limitations. We study three 4B backbones and four benchmarks, with one training seed per configuration; whether the two failure signatures generalize to other scales, reward designs and corruption regimes is open. Refusals are detected by keyword matching on the final answer, which can miss paraphrased refusals and count hedged answers as refusals. The answerability probe and the reasoning transplant were run on Qwen3-VL-4B only. LATCH reads a single layer with a fixed cut-off and judges the input rather than the answer, so it can override a correct reading of a blurry but legible image; adaptive, multi-layer cut-offs are natural extensions.

LLM Usage Statement

[TODO: Replace with an accurate statement of how LLMs were used. Draft, to be checked: We used an LLM-based coding assistant to check the manuscript for consistent terminology and notation, to fix typesetting errors, and to check bibliography entries against their arXiv and venue pages. All research ideas, experiments, analyses and conclusions are the authors' own, and the authors reviewed every change.]

Seeing Better but Knowing Less: Corruption-Robustness Fine-Tuning Silently Erodes Visual Abstention in Vision-Language Models

Supplementary Material

A. Evaluation Protocol

This section specifies everything needed to reproduce the numbers in the main paper: the prompts, how answers are decoded and extracted, how they are scored, how refusals are detected, and how each benchmark is built. All models, base and fine-tuned, are evaluated with the identical protocol.

A.1. Prompting

All three backbones (Qwen3-VL-4B, InternVL3.5-4B, Gemma-3-4B) and all of their fine-tuned variants receive the same system prompt, which is also the format used during training:

> You are a careful visual question-answering assistant. For each question about an image, first reason step by step about what you see inside <think> </think> tags. Then give your final answer inside <answer> </answer> tags, as a single word or short phrase.
> Your response must use exactly this format:
> <think> your reasoning </think>
> <answer> your final answer </answer>

The user turn contains the image followed by the question, verbatim. For VizWiz, and for TextVQA-Paired (Sec. A.7), we append the following sentence to the question so that the model knows abstention is an allowed answer:

> If the image does not contain enough information to answer, the answer is unanswerable.

The TextVQA-C, GQA-C and VQAv2-C questions carry no such note, which matches how these benchmarks are normally evaluated. In the no-image setting the image is withheld entirely: no image tokens are given, while the system prompt and question are unchanged.

A.2. Decoding

Generation is greedy (temperature 0) with a budget of 768 new tokens and a context length of 18,432 tokens, run with vLLM 0.31.0 on a single GH200 GPU per run (seed 0). Greedy decoding makes every number deterministic, so no confidence intervals over sampling seeds are needed. The steering experiments (Sec. D) need forward hooks on the residual stream that vLLM does not expose, so they run in HuggingFace generate instead. They also decode greedily, with 384 new tokens; their unsteered rows were checked against the vLLM results for the same checkpoint.

A.3. Answer extraction and normalization

The final answer is extracted from the completion by the first rule that applies:

1. the content of the last <answer>…</answer> block after the reasoning;
2. otherwise, the content of the last \boxed{};
3. otherwise, the text after the last line of the form "(final) answer (is):";
4. otherwise, the last non-empty line, if it has at most 8 words;
5. otherwise, the empty string, which is always scored as wrong (e.g. a reasoning loop cut off at the token limit).

Rules 2–5 exist so that a model is not penalized only for formatting. After training, more than 99.9% of completions are handled by rule 1; we report the per-model rate at which each rule fires in the full result files. Both the prediction and the reference answers are then normalized with the standard VQA procedure: lowercasing, stripping punctuation and markdown emphasis, converting number words to digits, removing articles, and fixing common contractions.

A.4. Scoring

Correctness. A TextVQA, VQAv2 or VizWiz prediction is correct if its normalized form exactly matches any of the 10 normalized annotator answers. A GQA prediction is correct if it exactly matches the single reference answer. For completeness, the full tables also give the official soft VQA accuracy, min(#matches/3, 1); it does not change any ranking or conclusion in the paper.

Refusal detection. A prediction counts as a refusal (abstention) if its extracted answer, lowercased, contains any of the following strings:

> unanswerable, cannot, unable, not possible, no image, not visible, not provided, not determin, impossible.

We match only the extracted answer, not the reasoning. Otherwise a model that writes "the text is not visible at first, but…" and then answers would be wrongly counted as abstaining.

Strict rule. On answerable questions a refusal is always scored as wrong, even when an annotator answer happens to contain a refusal word (some VizWiz annotators answer "unanswerable" for questions that most annotators could answer). This stops a model from gaining accuracy by abstaining more. Every accuracy in the paper uses this rule.

A.5. Metrics

Corrupted / clean accuracy. Accuracy on the corrupted (resp. clean) view, averaged with equal weight over TextVQA-C, GQA-C and VQAv2-C, so that GQA's larger size does not dominate. This is the robustness metric (e.g. 64.3 → 71.8 for Qwen3-VL-4B base → GRPO).

Ans. acc. Strict accuracy on the answerable VizWiz questions.

UR (unwarranted refusal). Refusal rate on the answerable VizWiz questions. Lower is better.

CR (correct refusal). Refusal rate on the unanswerable VizWiz questions, i.e. the abstention rate (e.g. 71.6 → 44.9). Higher is better.

Unans. acc. Accuracy on the unanswerable VizWiz questions, scored against the annotator answers as above. Unlike CR, it requires the exact annotator wording.

No-image refusal. Refusal rate on the clean questions of the three corrupted benchmarks when the image is withheld. Since no image is given, the correct behaviour is to abstain on almost every question; a drop in this rate means the model answers from language priors alone.

A.6. Benchmarks

Corrupted benchmarks. TextVQA-C, GQA-C and VQAv2-C follow the corruption protocol of Usama et al. [54]. Each question is paired with its clean image and one corrupted copy. The corruption is drawn deterministically (a seed derived from the question id) from 19 ImageNet-C-style corruptions in four categories, with severity uniform over 1–5:

- noise: Gaussian, shot, impulse, speckle;
- blur: defocus, glass, motion, zoom, Gaussian;
- weather: snow, frost, fog, brightness, spatter;
- digital: contrast, elastic transform, pixelate, JPEG, saturate.

Corruption types and severities are balanced across each benchmark (Tab. S1). Eight of these types have a counterpart among the training corruptions (Gaussian noise, Gaussian blur, motion blur, snow, fog, brightness/over-exposure, JPEG, pixelate) and are reported as seen; the other 11 are unseen. Every corrupted benchmark is disjoint from the GQA training images. We report results broken down by category, severity and seen/unseen in Sec. C.

VizWiz. VizWiz-VQA contains real photographs taken by blind and low-vision users, so it is naturally degraded and has no clean copy. Its unanswerable questions (the majority annotator answer is "unanswerable") are the only place in the evaluation where abstaining is the correct behaviour. We use the full validation split.

A.7. TextVQA-Paired

TextVQA-Paired asks each question about three images: the original, a removed version in which every occurrence of the answer text is inpainted away, and a control version in which a region of identical shape elsewhere in the image is inpainted the same way. Prompting, decoding, extraction and refusal detection are exactly as above. We report:

Orig. / control acc. Strict accuracy on the original and control images.

Removed abstention. Refusal rate on the removed images (higher is better).

Removed still correct. How often the model still outputs the answer after it was removed; this measures leakage of evidence the edit missed.

Paired consistency. The fraction of questions on which the model is correct on both the original and the control image and abstains on the removed image, i.e. the ideal behaviour on all three views at once.

The headline numbers exclude the 3 items flagged in the visual audit because the answer is still printed elsewhere in the image, and the 29 items whose answer can be guessed from the question alone, which are reported separately. This leaves 468 questions.

A.8. Robustness of the protocol

To check that our conclusions do not depend on the refusal word list, we re-score all models with (i) a reduced list containing only unanswerable and (ii) an extended list that adds hedges such as unclear, not sure and can't tell. The trade-off holds under both lists: corrupted accuracy rises and CR falls after fine-tuning for every backbone.

Benchmark	Source split	Views	#Q	#Q seen corr.
TextVQA-C	TextVQA val (all)	clean + corrupted	5,000	2,104
GQA-C	GQA test-dev balanced (all)	clean + corrupted	12,578	5,294
VQAv2-C	VQAv2 val (random subset)	clean + corrupted	5,000	2,107
VizWiz	VizWiz-VQA val (all)	real photos	4,319	–
answerable			2,934	
unanswerable			1,385	
TextVQA-Paired	TextVQA val (500 questions)	orig / removed / control	1,500	–

Table S1. Evaluation benchmarks. "Seen corr.": questions whose corruption type also appears in the training corruptions.

B. Training Details

We fine-tune three 4B-scale backbones, Qwen3-VL-4B-Instruct, InternVL3.5-4B (HF format) and Gemma-3-4B-it, with two answer-focused objectives: GRPO (Sec. B.2) and on-policy reverse-KL distillation from a larger teacher of the same family (RKL, Sec. B.3). All runs are full fine-tuning (every weight, including the vision encoder), use the same training questions, and share one set of optimization hyperparameters (Tab. S2). Only the objective-specific settings differ.

B.1. Training data

Corrupted GQA (main runs). We sample 30,000 questions from the GQA train split. Every question is paired with its clean image and one corrupted copy at severity 4 (of 5). The corruption is one of 16 styles, each used for exactly 1,875 questions: Gaussian noise, Gaussian blur, motion blur, zoom blur, pixelate, JPEG, fog, snow, rain, over-exposure, night, dusk, shadow, static occlusion, rotation and translation. Training images come from GQA train and every evaluation image from GQA test-dev, TextVQA, VQAv2 or VizWiz, so no image is shared. The training corruptions come from our own engine, not the ImageNet-C implementation used at test time, so even the eight seen test corruptions (Sec. A.6) are produced by different code. GQA answers are short (yes/no: 35%), and every training question is answerable. The corrupted GRPO and RKL runs train on the corrupted copy only; RKL also shows the clean copy to the teacher (Sec. B.3).

Unanswerable mix ("10%" runs). To test whether adding unanswerable examples to training repairs abstention, we add 3,334 destroyed questions to the 30k set, so they make up 10% of the resulting 33,334. Each is a GQA train question on an image used nowhere else (not in training, evaluation or the steering calibration pool), which we corrupt far beyond the 1–5 scale until the image carries no usable content. Seven styles are cycled equally: Gaussian noise, Gaussian blur, motion blur, over-exposure, rain and night at severity 100, and snow at severity 50. The target answer is unanswerable. Every question in this mix, answerable or not, carries the VizWiz note (Sec. A.1), so the model learns that abstention is an allowed answer. For a destroyed item the clean image is the destroyed image itself, so an RKL teacher sees the same destroyed image as the student. These runs keep the main runs' budget of 3,750 optimizer steps (30,000 questions), so they see 90% of the mix. Fig. S1 shows the pipeline.

Clean-image control. To measure how much training on corrupted images contributes to the loss of abstention, beyond answer-focused training itself, we repeat the Qwen3-VL-4B GRPO run with every training image replaced by its clean original. The questions, their order, the seed and every hyperparameter stay the same.

B.2. GRPO

For each question the current policy samples G=8 completions from the corrupted image at temperature 1, with no teacher and no clean image. A completion receives reward

$$r_i = \mathbb{1}[\hat{a}_i = a^\star] + 0.1\,\mathbb{1}[\text{well-formed}_i], \qquad (11)$$

where $\hat{a}_i$ is the normalized extracted answer, $a^\star$ the GQA answer (exact match, Sec. A.3), and well-formed means the completion contains exactly one <answer>…</answer> block and ends right after it. Under this strict reward a correct answer in a malformed completion earns nothing. Without it, our first full fine-tuning runs collapsed into degenerate outputs (the answer followed by junk or repetition) that a lenient reward still paid for. Rollouts stop at </answer>. Advantages are normalized within each group, $A_i = (r_i - \bar{r})/(\sigma_r + \epsilon)$, and groups whose rewards are all equal (zero advantage) are skipped. The per-token loss is the clipped policy-gradient objective (ϵ_{clip}=0.2) plus a per-token KL penalty to a frozen copy of the starting policy (the k_3 estimator, β=0.04), averaged over all completion tokens in the optimizer step.

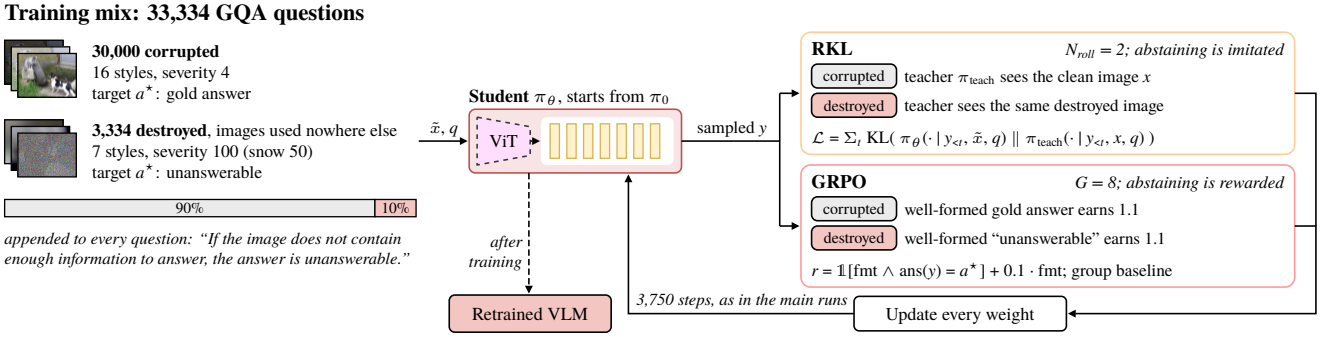

Figure S1. Unanswerable-mix retraining. The base model is retrained from scratch with the recipe and budget of the main runs, on a mix in which 10% of the questions are GQA items on destroyed images with the target "unanswerable". RKL imitates a teacher that sees the same destroyed image; GRPO rewards a well-formed refusal. Unlike LATCH and steering, this remedy changes the weights.

B.3. On-policy reverse-KL distillation (RKL)

The student samples 2 completions per question from the corrupted image (temperature 1). A frozen teacher of the same family then scores the student's own tokens while seeing the clean image under the identical prompt. Because the corruptions keep the image resolution, the two inputs tokenize to the same length and the teacher's distribution at position t conditions on the same prefix as the student's. The teachers are Qwen3-VL-8B-Instruct, InternVL3.5-14B-HF and Gemma-3-12B-it. For InternVL we use the 14B model because the 8B was weaker than the 4B student under our prompt (GQA clean 54.8 vs. 58.8 for the 14B; VizWiz unanswerable 63.3 vs. 75.5). The teacher scores the exact token ids that vLLM sampled; re-tokenizing the decoded text would merge > with the first answer token and leave that token untrained.

Following EOPD, the loss at each completion token x_t is the clipped policy-gradient form of the reverse KL,

$$A_t = \log \pi_T(x_t) - \log \pi_{\text{old}}(x_t),$$
$$\mathcal{L}_t = \max\big(-\rho_t A_t,\ -\text{clip}(\rho_t, 1-\epsilon, 1+\epsilon) A_t \big), \tag{12}$$

with $\rho_t = \pi_\theta(x_t)/\pi_{\text{old}}(x_t)$, ϵ=0.2 and A_t detached. EOPD's optional forward-KL term on entropy-gated tokens is switched off, so the objective is pure reverse KL. There is no extra reward, no format bonus and no access to the gold answer.

Gemma: exact reverse KL. With this one-sample estimator the Gemma-3-4B student grew a diffuse tail of tokens to which the teacher gives almost zero probability. Around step 1,600 the exact KL to the teacher rose from 0.5 to 3.8 while the sampled estimate stayed near 0, and samples at temperature 1 became garbage. We therefore also train Gemma with the exact full-vocabulary reverse KL, $\mathcal{L}_t = \sum_x \pi_\theta(x)\,[\log \pi_\theta(x) - \log \pi_T(x)]$ ("RKL-full"), which penalizes tokens the student rarely samples directly. The main RKL-full run resumes the sampled-RKL run from its step-1,250 checkpoint, before the breakdown, and continues with the exact loss to step 3,750. The 10% variant uses the exact loss from the start. We report both Gemma objectives.

B.4. Optimization and infrastructure

Hardware. Each run uses two NVIDIA GH200 GPUs: one trains the policy, and the other hosts both the vLLM rollout server and the frozen teacher (RKL) or KL reference (GRPO). The policy pushes its full weights to the vLLM server every 10 optimizer steps, so rollouts are at most 10 steps behind the current policy. Each rollout contributes exactly one gradient update, so the importance ratio ρ_t equals 1 in value and only shapes the gradient. A 3,750-step run takes 20–26 hours (Qwen3-VL-4B GRPO: 20.4 s per step on average).

Resuming. Our cluster limits jobs to 24 hours, so runs that did not finish were resumed from their last checkpoint (Tab. S3). A resumed run replays the seeded data shuffle and skips the questions already consumed, so every run sees each training question exactly once and in the same order. The learning-rate schedule continues from the resume step. For GRPO, the KL reference remains the original starting model, not the checkpoint. Checkpoints store weights only, so the Adam moments restart at each resume.

Training dynamics. In the clean-image control, a single step (629) produced a large update (KL 49.7, gradient norm 188 before clipping); clipping bounded the update, and KL returned to 0.2–0.4 on the following

Shared by every run	
Fine-tuning	full (all weights, incl. vision encoder)
Precision	bf16 weights; fp32 gradients and Adam moments
Optimizer	AdamW, stochastic rounding into bf16
Learning rate	1×10^{-6}, cosine, 10% linear warm-up
Weight decay	0.01
Gradient clipping	global norm 1.0
Batch	8 questions per optimizer step
Steps	3,750 (= 1 epoch of 30k questions)
Loss aggregation	mean over completion tokens of the step
Max completion	512 tokens
Rollout sampling	temperature 1.0, top-p 1.0
Rollout engine	vLLM; policy weights synced every 10 steps
Prompt	think_answer system prompt (Sec. A.1)
Seed	0
GRPO	
Rollouts / question	8
Reward	strict exact match + 0.1 well-formed
Advantage	group mean / std; zero-advantage groups skipped
Clip ϵ	0.2
KL to start policy	k_3, $\beta = 0.04$
Stop sequence	</answer>
RKL distillation	
Rollouts / question	2
Teacher	Qwen3-VL-8B / InternVL3.5-14B / Gemma-3-12B (clean image)
Loss	clipped PG reverse KL ($\epsilon = 0.2$); Gemma also exact RKL
Forward-KL term	off

Table S2. Training hyperparameters. One set of settings is used for every backbone; no per-model tuning was done.

Backbone	Objective	Data	Teacher	Resumed at step
Qwen3-VL-4B	GRPO	corrupted 30k	–	–
	GRPO	clean 30k	–	(in progress)
	GRPO	10% mix	–	–
	RKL	corrupted 30k	Qwen3-VL-8B	–
	RKL	10% mix	Qwen3-VL-8B	–
InternVL3.5-4B	GRPO	corrupted 30k	–	2500
	GRPO	10% mix	–	2500
	RKL	corrupted 30k	InternVL3.5-14B	2500
	RKL	10% mix	InternVL3.5-14B	2500
Gemma-3-4B	GRPO	corrupted 30k	–	2875
	GRPO	10% mix	–	1750, 3125
	RKL	corrupted 30k	Gemma-3-12B	1875
	RKL-full	corrupted 30k	Gemma-3-12B	1250†, 1850, 2800
	RKL-full	10% mix	Gemma-3-12B	1400, 2800

Table S3. All training runs. Every run lasts 3,750 optimizer steps and is evaluated at its final checkpoint. †Switch from sampled to exact reverse KL (Sec. B.3).

step with no change in rollout accuracy.

C. Full Results

This section reports every backbone and training variant on every benchmark, broken down by corruption

category, severity and whether the corruption was seen in training, together with the full abstention metrics and the no-image setting. "GRPO" and "RKL" are the main runs on corrupted GQA; "-10%" marks the runs trained on the mix with 10% unanswerable questions (Sec. B.1); "RKL-full" is Gemma trained with the exact reverse KL (Sec. B.3).

C.1. Accuracy on every benchmark

Tab. S4 gives clean and corrupted accuracy per benchmark. Two observations matter for interpreting the robustness gains in the main paper.

The gains are general, not corruption-specific. Fine-tuning raises clean accuracy almost as much as corrupted accuracy. For the main GRPO runs, corrupted accuracy rises by +7.6 (Qwen), +6.6 (InternVL) and +5.2 (Gemma) points while clean accuracy rises by +6.9, +6.4 and +3.9, so the clean-to-corrupted drop shrinks by only 0.2–1.3 points. RKL shows the same pattern (drop reduced by 0.0–2.1 points). Under the standard definition (accuracy on corrupted inputs) the models are more robust, but most of the gain comes from answering better in general rather than from closing the gap caused by corruption. The clean-image control (Sec. B.1) tests directly whether the corrupted training images contribute to the loss of abstention.

Exceptions. Gemma's sampled-RKL run is the only variant that loses accuracy (−1.4 corrupted, −1.3 clean), consistent with the breakdown of the sampled estimator described in Sec. B.3; the exact-KL run (RKL-full) recovers a +3.5 gain. Gemma GRPO and GRPO-10% lose 5.0 and 2.1 points of clean TextVQA accuracy while gaining on GQA and VQAv2, the only per-benchmark regressions among the GRPO runs, possibly because the GQA training questions contain almost no scene text.

C.2. Abstention and the no-image setting

Tab. S5 gives all four VizWiz metrics and the refusal rate without an image.

Every main run abstains less where it should. Correct refusals on unanswerable VizWiz questions fall for every backbone and both objectives: by 26.7 / 22.0 points (Qwen GRPO / RKL), 32.6 / 24.6 (InternVL) and 17.3 / 16.0 / 16.3 (Gemma GRPO / RKL / RKL-full). Unwarranted refusals on answerable questions fall too (−3.0 to −9.5 points), so the models do not become more selective; they refuse less across the board, and answerable accuracy rises partly because of this.

The no-image probe. With the image withheld, the correct behaviour is to refuse. On the three corrupted benchmarks, whose prompts do not mention abstention, base Qwen3-VL-4B refuses on 52.0% of questions; after GRPO or RKL it refuses on 0.5% and 1.0%, i.e. it answers almost every question from the text alone. InternVL and Gemma rarely refuse here even before training (2.0% and 2.1%) and fall to near 0% afterwards. When the prompt explicitly allows "unanswerable" (VizWiz questions without their image), the picture depends on the objective: the GRPO models still refuse most of the time (Qwen 87.1%, InternVL 76.1%), whereas RKL collapses no-image refusal (Qwen 98.3% → 23.2%, InternVL 73.6% → 32.5%). Gemma refuses rarely in every setting. So after GRPO the models can still refuse when told explicitly that they may and the image is absent, but no longer do so unprompted, nor when an image is present but uninformative (CR above).

Adding unanswerable examples helps only partly. Training with 10% unanswerable questions keeps the accuracy gains (within 0.5 points of the main run for GRPO) but recovers abstention unevenly. RKL-10% recovers most: CR returns to 61.7 (Qwen, base 71.6) and exceeds the base on InternVL (62.7 vs. 58.6), but at the cost of more unwarranted refusals (InternVL UR 14.6 vs. 11.3 for the base). GRPO-10% recovers little: CR is 56.9 (Qwen), 31.2 (InternVL) and 14.7 (Gemma), still 14.7, 27.4 and 13.5 points below the base. Only Qwen GRPO-10% partially restores no-image refusal (31.4%). Training on destroyed images thus restores refusals only partly and inconsistently across backbones, and on the benchmarks whose prompts do not mention abstention it does not bring back the base model's refusal without an image (at best 31.4% vs. 52.0% for Qwen).

C.3. Breakdown by corruption

Tab. S6 splits corrupted accuracy by category and by whether the corruption type appears in training, and Tab. S7 by severity.

Seen vs. unseen. Gains on unseen corruption types match those on seen types for every variant (within 0.7 points; e.g. Qwen GRPO +7.4 seen vs. +7.7 unseen, InternVL GRPO +6.6 vs. +6.7). Combined with the near-equal clean gains above, this indicates that the models are not learning to undo specific corruptions they were trained on.

Category and severity. For GRPO the gains are spread evenly over the four categories (within 1.6

Backbone	Model	TextVQA-C clean	TextVQA-C corr.	GQA-C clean	GQA-C corr.	VQAv2-C clean	VQAv2-C corr.	Mean clean	Mean corr.	Mean drop
Qwen3-VL-4B	Base	81.3	67.9	55.8	51.9	79.2	73.0	72.1	64.3	7.8
	GRPO	84.6	71.0	65.4	62.1	87.0	82.5	79.0	71.8	7.2

Table S5. Abstention behaviour. VizWiz: strict accuracy on the 2,934 answerable questions, unwarranted refusals (UR) on them, correct refusals (CR) on the 1,385 unanswerable questions, and annotator-match accuracy on the unanswerable questions. No image: refusal rate when the image is withheld, averaged over the clean questions of TextVQA, GQA and VQAv2, and on VizWiz. Parentheses: change from the base model of the same backbone.

points on every backbone); RKL gains are less even, e.g. smallest on weather for InternVL (+3.8 vs. +6.6 on noise) and largest on blur for Qwen. The gains grow slightly with severity: Qwen GRPO gains +6.5 points at severity 1 and +9.4 at severity 5, InternVL GRPO +5.8 and +7.0, Gemma GRPO +3.9 and +6.2, so a small part of the improvement is specific to heavily degraded inputs.

Table S8. Mean accuracy (%) under our any-annotator-match rule and under the official soft VQA accuracy, $\min(\#\text{matches}/3, 1)$, for TextVQA and VQAv2 (GQA has a single answer and is scored identically). Refusals count as wrong in both.

C.4. Official soft VQA accuracy

Tab. S8 re-scores every model with the official soft accuracy. Absolute numbers are lower, because a prediction matching only one or two annotators earns partial credit, but every gain changes by at most 0.5 points and no ranking changes.

D. Steering and LATCH Sweeps

The main paper tests two inference-time ways to restore abstention without retraining: activation steering, which adds a fixed direction to the residual stream during decoding, and LATCH (LATent CHeck), which

reads an answerability probe and replaces the answer with "unanswerable" when the probe fires. Each has one strength knob: the steering strength λ and the probe cut-off τ. This section describes both methods and reports the full sweeps.

D.1. Methods

Steering directions. All directions are computed on a calibration pool drawn from the training splits (VizWiz-train and GQA-train questions), which share no question or image with the test sets. For each fine-tuned model we build two directions per decoder layer l:

- contrast: on unanswerable calibration questions where the base model abstains and the fine-tuned model answers, we teacher-force the fine-tuned model's answer through both models and take the mean residual difference over the response tokens, $v_l = \mathbb{E}_t[h^{\text{base}}_{l,t} - h^{\text{ft}}_{l,t}]$. At λ=1 this moves a fine-tuned activation onto the base model's average position.
- no-image: on calibration questions asked without their image, where the base model refuses and the fine-tuned model answers, we pass both responses through the fine-tuned model and take the mean difference between the refusal and the answer.

Applying steering. At decoding step t we add λv_l to the output of layer l=18 for the token being processed. The vector is added either at every step ("always") or only when the entropy of the previous step's next-token distribution exceeds 0.5 nats ("H>0.5"), so that confident tokens are left alone. Directions differ in norm across models, so λ is nominal: each model's λ is rescaled so that $\|\lambda v_{18}\|$ equals the norm of the same nominal λ applied to one fixed reference vector (from a Qwen3-VL-4B RKL model). One nominal λ therefore means the same perturbation size for every model. Fig. S2 shows both stages for the contrast direction.

LATCH. A class-balanced logistic-regression probe (inputs standardized, L2 weight 0.1) is trained to predict "unanswerable" from the last-prompt-token residual of layer 24, using the 1,901 VizWiz-train calibration questions (1,101 unanswerable, 800 answerable). At test time the model first decodes as usual; if the probe logit on the input exceeds τ, its answer is replaced by <answer>unanswerable</answer>. τ=0 corresponds to a predicted probability of 0.5, and a larger τ fires less often. LATCH never changes the answer on inputs where the probe does not fire, so its cost is exactly the answerable questions on which it wrongly fires.

D.2. Steering strength sweep

Validation sweep. Tabs. S9 and S10 sweep λ for both directions and both gates on a validation set of 100 VizWiz-train questions (50 answerable, 50 unanswerable). These questions come from the calibration pool, so they are disjoint from the test sets but not from the data the directions were computed on, and with 50 questions per half the sweep resolves only large effects (one question is 2 points). Three patterns are consistent across models:

- Too much steering breaks generation. Always-on no-image steering at λ=4 drives answerable accuracy to 0% for Qwen GRPO, Qwen RKL, both InternVL models and Gemma RKL-full (the model stops producing a usable answer), and Qwen RKL already breaks at λ=2. This sets the upper end of the useful range.
- The no-image direction is stronger than the contrast direction at equal norm. For Qwen GRPO, always-on no-image steering at λ=1 raises CR from 42 to 62 while the contrast direction stays between 32 and 42 at every λ.
- Gating weakens the effect. The entropy gate steers 13–57% of decoding steps, and at the same λ it changes CR less than always-on steering.

Test results. Tab. S11 reports every configuration we evaluated on the full test sets. Steering helps the Qwen models and InternVL RKL, but always at a cost:

- Qwen GRPO: always-on no-image steering (λ=1) raises CR from 44.9 to 70.7 and keeps corrupted accuracy almost unchanged (72.0 → 71.7), but UR rises from 3.2 to 14.5.
- Qwen RKL: the same setting reaches CR 88.6, but UR rises to 45.4 and corrupted accuracy falls from 66.4 to 57.5. The gated version is milder (CR 76.0, UR 24.5, corrupted 64.6).
- InternVL RKL: CR rises from 33.9 to 72.6, with UR 7.1 → 28.8.
- InternVL GRPO and all Gemma models barely respond: the best CR is 40.8 (InternVL GRPO, from 25.8) and 36.5 (Gemma GRPO, from 10.5, at λ=4 with answerable accuracy down 6.9 points).

No steering configuration restores refusal without an image: it stays at or below 4.2% everywhere except Qwen RKL at its strongest setting (26.1%). Steering restores abstention on VizWiz-like inputs only for some models, and does not bring back a general sensitivity to missing evidence.

D.3. LATCH cut-off sweep

The probe still detects unanswerable inputs. Tab. S13 shows that a linear probe recovers answerability from

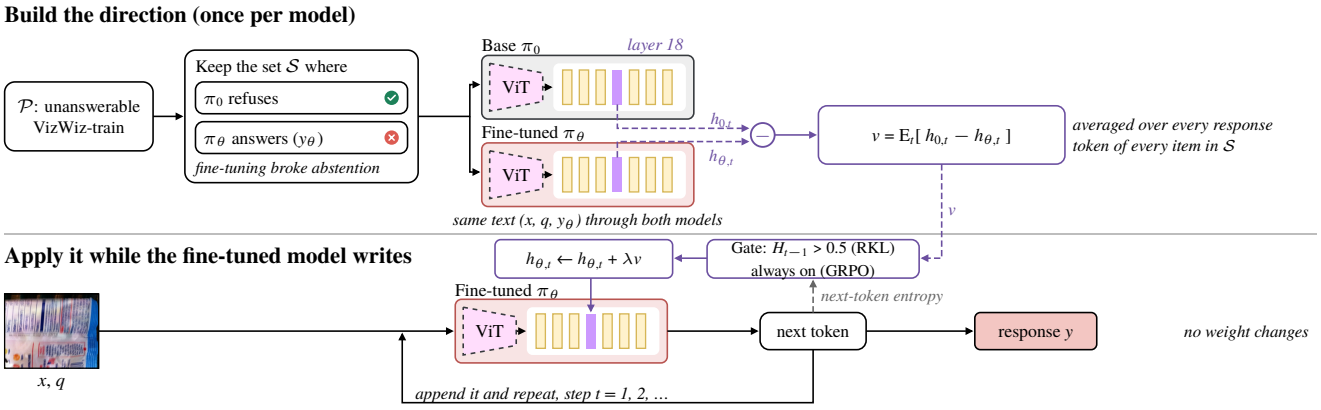

Figure S2. Contrastive activation steering. Top: the direction v is the mean difference between the layer-18 states of the base and fine-tuned models, $h_{0,t}$ and $h_{\theta,t}$, on questions where fine-tuning broke abstention. Bottom: while the fine-tuned model generates, λv (the strength α of Alg. 2) is added at layer 18 on each generated token, after an entropy gate for RKL and always for GRPO. The no-image direction replaces the top row by the difference between a base refusal and a fine-tuned answer, both passed through the fine-tuned model.

every fine-tuned model with AUROC 0.90–0.93 on VizWiz-val, even though these models rarely say "unanswerable". The probe layer was chosen by cross-validation on the calibration set only. Layer 24 is best for both Qwen models, and for InternVL and Gemma it is within 0.007 CV AUROC of their best layer, so we use layer 24 for every model.

The cut-off traces a smooth trade-off. Tab. S12 sweeps τ. Lowering τ monotonically raises CR and UR and lowers corrupted accuracy, because LATCH wrongly fires on more answerable questions. For Qwen GRPO:

- τ=2, the setting reported in the main paper: CR rises from 44.9 to 61.2, with UR 3.2 → 5.4 and corrupted accuracy 72.0 → 71.4. Only 0.6% of clean answerable benchmark questions are overridden.
- τ=0: CR reaches 87.3, at the cost of UR 17.2 and corrupted accuracy 66.7.

Unlike steering, LATCH works on every backbone. At τ=2:

- InternVL GRPO: CR 25.8 → 56.6, UR 2.6 → 5.4, corrupted accuracy −0.2;
- Gemma GRPO: CR 10.5 → 43.1, UR 0.5 → 2.9, corrupted accuracy −1.2.

It also partly restores refusal without an image: 31.6% for Qwen GRPO at τ=2 (0.5% without LATCH), and above 90% for Gemma GRPO, whose probe fires on almost every image-free input.

Steering vs. LATCH at matched cost. At a similar unwarranted-refusal rate LATCH recovers more abstention but costs more benchmark accuracy. For Qwen GRPO:

- LATCH at τ=0.5: CR 81.7, UR 13.5, corrupted accuracy 68.8;
- always-on no-image steering at λ=1: CR 70.7, UR 14.5, corrupted accuracy 71.7.

LATCH's extra cost comes from overriding corrupted answerable questions that the model would have answered correctly. Steering changes the model's own decision and leaves most of these answers intact. Neither method returns the model to the base model's operating point: base Qwen3-VL-4B reaches CR 71.6 at UR 12.8 with corrupted accuracy 64.3. LATCH and steering both keep most of the fine-tuned accuracy while recovering part of the abstention, which is the sense in which we call the recovery partial.

E. Qualitative Examples

This section shows what the numbers in the main paper look like on individual inputs. We picked examples that illustrate each pattern clearly; they are not a random sample. Rates for each pattern are given in the referenced sections.

E.1. Unanswerable VizWiz questions

Fig. S3 shows two unanswerable VizWiz questions. In both, the base model abstains. The GRPO model's reasoning reaches the same conclusion, that the image is too blurry to tell, yet its final answer is a guess ("book", "water"). Both inference-time fixes recover the abstention. No-image steering (λ=1, always on) changes the generated answer itself. LATCH overrides it: the probe logit is 3.86 and 3.59, above the cut-off τ=2.

Model	Gate	λ=0	2	4	6	8	12	16
Qwen GRPO	always	42/64	42/64	42/58	42/60	40/62	38/60	38/44
	H>0.5	42/64	38/64	42/60	40/64	38/64	38/64	32/56
Qwen RKL	always	38/60	40/56	42/54	46/60	54/46	56/48	82/28
	H>0.5	38/60	40/52	42/52	48/56	46/54	40/58	38/60
InternVL GRPO	always	24/48	24/46	26/52	26/52	26/54	28/52	28/50
	H>0.5	24/48	24/48	24/46	24/46	24/46	24/46	24/46
InternVL RKL	always	26/50	26/52	24/46	26/54	26/50	30/48	24/44
	H>0.5	26/50	30/48	26/48	26/52	28/50	28/46	22/50
Gemma GRPO	always	8/44	10/42	8/42	8/42	6/42	6/42	8/40
	H>0.5	8/44	10/44	8/44	10/42	6/40	8/40	8/40
Gemma RKL-full	always	12/42	12/42	12/42	8/42	10/38	12/40	10/46
	H>0.5	12/42	12/42	10/44	12/44	10/42	8/40	14/46

Table S9. Steering-strength sweep on the validation set (100 VizWiz-train questions from the calibration pool, 50 answerable and 50 unanswerable; disjoint from every test set but not from the pool the directions were computed on), contrast (base-vs-fine-tuned) direction, layer 18. Each cell: correct refusals on the unanswerable half / strict accuracy on the answerable half (%). λ is the nominal strength before norm matching (Sec. D.1); "always" steers every decoding step, H>0.5 only steps whose next-token entropy exceeds 0.5. With 50 questions per half, one question is 2 points.

Model	Gate	λ=0	0.25	0.5	1	2	4
Qwen GRPO	always	42/64	44/64	46/66	62/66	40/28	4/0
	H>0.5	42/64	40/66	44/62	44/64	44/58	4/0
Qwen RKL	always	38/60	46/50	52/46	80/38	0/0	0/0
	H>0.5	38/60	42/52	44/46	62/44	72/8	0/0
InternVL GRPO	always	24/48	24/48	24/48	24/46	40/46	0/0
	H>0.5	24/48	24/48	24/48	24/46	24/46	28/40
InternVL RKL	always	26/50	34/48	32/40	60/44	96/12	0/0
	H>0.5	26/50	30/48	28/48	40/44	80/30	62/24
Gemma GRPO	always	8/44	10/40	8/40	12/44	18/42	24/38
	H>0.5	8/44	10/42	8/44	10/46	12/48	12/48
Gemma RKL-full	always	12/42	12/40	12/34	20/34	52/22	6/0
	H>0.5	12/42	10/42	16/42	16/42	52/26	8/8

Table S10. Steering-strength sweep on the validation set (100 VizWiz-train questions from the calibration pool, 50 answerable and 50 unanswerable; disjoint from every test set but not from the pool the directions were computed on), no-image direction, layer 18. Each cell: correct refusals on the unanswerable half / strict accuracy on the answerable half (%). λ is the nominal strength before norm matching (Sec. D.1); "always" steers every decoding step, H>0.5 only steps whose next-token entropy exceeds 0.5. With 50 questions per half, one question is 2 points.

Reasoning says "unanswerable", the answer does not. The pattern in Fig. S3 is common after GRPO. Among unanswerable VizWiz questions that Qwen GRPO answers anyway, 27.8% (212 questions) have reasoning that itself states the question cannot be answered (e.g. "cannot determine", "too blurry to identify", "unanswerable"; keyword heuristic), compared with 4.6% for the base model and 1.9% for Qwen RKL. This is consistent with GRPO rewarding only the final answer: producing an answer is reinforced even when the model's own reasoning concludes that it should not. This is direct evidence for the gap the probe exploits: the information needed to abstain is still present, but no longer reaches the output.

E.2. TextVQA-Paired

Fig. S4 shows two TextVQA-Paired questions on which the base and GRPO models give the correct answer on both the original and the control image, so they can read the evidence and are not disturbed by the edit

image missing	Q: What is this package? (unanswerable) Base: The image is too blurry and lacks sufficient detail to identify what the package is. […] unanswerable ✓ GRPO: The image is too blurry to identify the package. There are no clear visual cues to determine what the package is. book ✗ GRPO + steering: The image is too blurry to determine what package it is. […] unanswerable ✓ GRPO + LATCH: probe logit 3.86 > τ=2 ⇒ unanswerable ✓
image missing	Q: What's in this bottle? (unanswerable) Base: The image is too blurry to determine what's inside the bottle. The text on the bottle is illegible […] Therefore, the answer is unanswerable. unanswerable ✓ GRPO: The image is too blurry to determine what is inside the bottle. The text on the bottle is illegible, and there is no clear visual indication of the contents. Therefore, the answer is unanswerable. water ✗ GRPO + steering: The image does not contain a bottle, so the question is unanswerable. unanswerable ✓ GRPO + LATCH: probe logit 3.59 > τ=2 ⇒ unanswerable ✓

Figure S3. Unanswerable VizWiz questions, Qwen3-VL-4B. After GRPO the model's reasoning still concludes that the question cannot be answered, but the final answer is a guess. Steering (no-image direction, λ=1, always on) and LATCH (τ=2) both restore the abstention. Note the steered reasoning in the second example ("does not contain a bottle"): the abstention is right, but the stated reason is not.

itself. They differ only on the removed image.

- License plate. With the plate on the yellow van removed, the base model says the plate is obscured and abstains. The GRPO model instead reads the plate of the white van in the background, "WG53 JNU". That plate is real, but it answers a different question than the one asked. The model substitutes the nearest available evidence rather than admitting that the requested evidence is gone.
- Jersey number. With the number removed, both models' reasoning notes that no number is visible. The base model abstains; the GRPO model answers "3". This is the same reasoning–answer mismatch as in Fig. S3.

The jersey example also shows the main weakness of the edit: the inpainted region is visible as a smooth patch. The control image carries an identical patch elsewhere and both models still answer correctly there, so the patch alone does not explain the behaviour on the removed image (Sec. F).

E.3. No image

When the image is withheld, the base model usually says so; the GRPO model often describes an image it was never shown (GQA question, no image, no abstention note):

> Q: What is hanging above the chalkboard? (gold: picture)
> Base: I don't see any image or visual content provided. Without an image to analyze, I can't determine what is hanging above the chalkboard. […] unable to determine
> GRPO: I need to examine the image to determine what is hanging above the chalkboard. Looking at the image, I can see a chalkboard in the center of the scene. Above it, there is a whiteboard or a similar surface. […] a whiteboard

This is the behaviour behind the collapse of no-image refusal from 52.0% to 0.5% (Tab. S5).

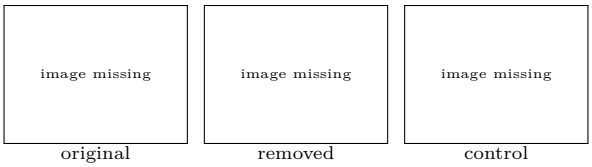

E.4. Failure cases of the fixes

Fig. S5 shows how each fix goes wrong, and one case where fine-tuning genuinely helps.

- Steering over-refuses. On an answerable question about a screen showing "Starting Windows", the GRPO model answers correctly. Under steering it reads the same text, then reasons that there is no error message and abstains. Steering pushes the model toward refusal on questions with a doubtful premise, one source of its unwarranted refusals (UR 3.2 → 14.5, Tab. S11).
- LATCH overrides correct answers. On a card showing "05/18" the GRPO model reads the date correctly, but the probe logit (2.29) exceeds τ=2 and the answer is replaced by "unanswerable". The probe judges the input, not the answer, so LATCH can fire on a blurry but readable image even when the model got it right.
- Fine-tuning fixes some unwarranted refusals. On a blurry photo of a blue skirt, the base model refuses. The GRPO model answers "blue" correctly, although its reasoning still says the question is unanswerable. The same mismatch that hurts on unanswerable questions helps here, which is why answerable VizWiz accuracy rises after training (40.6 → 60.9).

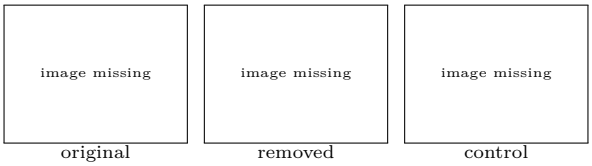

F. Limitations

Scale and coverage of models. We study three 4B-parameter backbones with teachers of at most 14B pa-

original removed control

Q: What is the license plate number of this vehicle? (gold: aj52uyv)
Original / control: base and GRPO both answer correctly on both images (GRPO: AJ52 UYV) ✓.
Removed, base: […] the license plate is blurred or obscured in the image, making it impossible to read the exact characters. unanswerable ✓
Removed, GRPO: The license plate on the white van in the background is visible and reads "WG53 JNU". WG53 JNU ✗

original removed control

Q: What is the number of the jersey in white? (gold: 16)
Original / control: base and GRPO both answer correctly on both images (GRPO: 16) ✓.
Removed, base: […] the number on the jersey is not visible in the image. Therefore, the number of the jersey in white cannot be determined […] unanswerable ✓
Removed, GRPO: […] I can see the name "STOJAKOVIC" printed across the shoulders. However, there is no visible number on the jersey. […] 3 ✗

Figure S4. TextVQA-Paired, Qwen3-VL-4B base vs. GRPO. Both models read the evidence on the original and control images; only the removed image separates them. GRPO either substitutes other evidence in the scene (top) or guesses despite its own reasoning (bottom).

Steering over-refuses. Q: Can you tell me what the error message is on the Windows screen? (gold: starting windows)
GRPO: The screen displays the text "Starting Windows" which is not an error message, but rather a normal startup message. […] Starting Windows ✓
GRPO + steering: The image shows a computer screen with the text "Starting Windows" displayed. There is no error message visible. […] unanswerable ✗

LATCH overrides a correct answer. Q: What's on this card? (gold: 05 18)
GRPO: The image is blurry, but it appears to show a portion of a document or card with text. The visible text includes: "MONTH/YEAR", "05/18" […] 05/18 ✓
GRPO + LATCH: probe logit 2.29 $>$ τ=2 $\Rightarrow$ unanswerable ✗

Fine-tuning fixes an unwarranted refusal. Q: What color is this skirt? (gold: blue)
Base: The image does not contain a skirt or any clothing item. […] it is not possible to determine the color of a skirt from this image. unanswerable ✗
GRPO: The image does not contain a skirt. […] Therefore, the question is unanswerable based on the provided image. blue ✓

Figure S5. Failure cases (VizWiz, answerable questions, Qwen3-VL-4B). Top: steering refuses on a question with a mistaken premise. Middle: LATCH overrides a correct reading. Bottom: the base model refuses wrongly and GRPO answers correctly, despite reasoning that says otherwise.

rameters. We do not know whether larger models, which abstain differently to begin with, lose abstention to the same degree. Each training configuration was run once (seed 0) with one set of hyperparameters shared by all backbones, so we cannot report variance across seeds, and some per-model differences (e.g. Gemma's failed sampled-RKL run) may depend on the recipe rather than the backbone.

Training data. All fine-tuning uses GQA questions with synthetic corruptions, and every question in the main runs is answerable. Our conclusion is that answer-focused fine-tuning on such data erodes abstention. Whether the same happens with training data that naturally contains unanswerable questions is only partly addressed by the 10% mix, which uses synthetically destroyed images rather than realistic unanswer-

able cases.

What the robustness gain is. Most of the accuracy gain on corrupted inputs is matched by a gain on clean inputs (Sec. C.1), and gains on unseen corruptions equal those on seen ones. The trade-off we report is therefore between general answer accuracy and abstention, measured on corrupted benchmarks, rather than a trade-off specific to corruption robustness. The clean-image GRPO control is designed to separate the two, but it covers one backbone only.

Measuring abstention. Refusals are detected with a fixed keyword list applied to the extracted answer (Sec. A.4). This misses hedged answers that contain none of the keywords and can, in principle, flag an answer that merely contains one. VizWiz is our only benchmark with naturally unanswerable questions, and it labels unanswerability by annotator majority, which is itself noisy. The no-image results depend on the prompt: with an explicit "unanswerable" option, the GRPO models still refuse most image-free VizWiz questions (Sec. C.2), so "no longer refuses without an image" holds only when abstention is not explicitly offered.

TextVQA-Paired. The paired benchmark covers only questions whose answer is a single printed word, so it tests text evidence, not objects, attributes or spatial relations. Removing evidence by inpainting leaves a visible patch (Fig. S4). The matched control patch rules out the patch itself as the cause of abstention, but it cannot rule out that a patch over the text region is a cue a model could learn. Items were kept only if an independent model (Qwen3-VL-8B) behaved as expected on them, which may bias the set toward cases that are easy for models of that family. The 29 items (5.8%) whose answer can be guessed from the question alone are reported separately; the independent checker still answered 3.2% of removed images correctly, all of them among these 29. Human verification of the set is in progress.

Inference-time fixes. The steering validation set has only 100 questions and is drawn from the same pool as the steering directions, and the probe cut-off τ=2 was not selected on held-out data, so the operating points we report are not tuned by a clean protocol. Both are better read as points on the trade-off curves in Sec. D. LATCH is a post-hoc override: it requires an extra probe trained on labelled unanswerable data, judges the input rather than the answer, and leaves the model's own behaviour unchanged. Steering changes the model's behaviour but does not transfer: it barely affects InternVL GRPO and any Gemma model.

Training procedure. Several runs were resumed after the 24-hour job limit, and each resume restarts the Adam moments (Sec. B.4). Data order and learning-rate schedule are preserved, but the resumed runs are not bit-for-bit identical to uninterrupted ones.

Statistical uncertainty. Decoding is greedy, so every number is deterministic for a given checkpoint, but we report no confidence intervals over questions. With 1,385 unanswerable VizWiz questions, a binomial 95% interval on CR is about ± 2.6 points at CR $= 50\%$, small compared with the 16–33 point drops we report, but comparable to some differences between variants (e.g. GRPO vs. GRPO-10% on Gemma).

Table S11. Every steering configuration evaluated on the full test sets (strict scoring). Corr./Clean: mean accuracy over TextVQA, GQA and VQAv2; Ans./UR/CR: VizWiz (Sec. A.5); No-img: refusal rate without the image; Steered: fraction of decoding steps on the corrupted and VizWiz inputs at which the steering vector was added. Rows with direction "none" are the unsteered model in the same (HuggingFace) pipeline.
